Glossary

Abdominoplasty Plastic surgery of the abdomen in which fat and skin are removed and muscles are sometimes tightened, usually for cosmetic purposes.

BRCA mutation Mutation in either of the BRCA1 and BRCA2 genes, which are tumor suppressor genes. Harmful mutations in these genes may produce a hereditary breast–ovarian cancer syndrome in affected persons.

Chondrolaryngoplasty Surgical procedure in which the thyroid cartilage is reduced in size by shaving down the cartilage through an incision in the throat, generally to aid those who are uncomfortable with the girth of their Adam's apple.

Pedicled flap An amount of tissue that is transferred, usually including skin and subcutaneous tissue, only partially removed from one part of the body so that it retains its own blood supply during transfer to another site.

Gender dysphoria (GD) Discomfort or distress that is caused by a discrepancy between a person's gender identity and that person's sex assigned at birth (and the associated gender role and/or primary and secondary sex characteristics).

Lipofilling Plastic surgery procedure in which tissue defects are filled with autografted fat tissue obtained through liposuction.

Mastopexy Surgical procedure in which the breasts are lifted or reshaped.

Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome Disorder that occurs in females and mainly affects the reproductive system. This condition causes the vagina and uterus to be underdeveloped or absent.

Orchiectomy Surgical procedure in which one or both testicles are removed.

Sex reassignment surgery (SRS) Also known as gender reassignment surgery (GRS), genital reconstruction surgery or gender confirmation surgery is the surgical procedure (or procedures) by which a gender dysphoric person's physical appearance and function of their existing sexual characteristics are altered to resemble that of their identified gender.

Symmastia Medial aspect of both breasts are bridged across the midline at the sternum because the pouches for breast implants were cut too close to the midline.

Standards of Care (SOC) for the health of transsexual, transgender, and gender-nonconforming people The overall goal of the SOC, provided by the World Professional Association for Transgender Health (WPATH), is to provide clinical guidance for health professionals to assist transsexual, transgender, and gender-nonconforming people with safe and effective pathways to achieving lasting personal comfort with their gendered selves, in order to maximize their overall health, psychological well-being, and self-fulfillment.

Transsexual A person having a strong desire to assume the physical characteristics and gender role of the opposite sex. This definition is still used for those patients who match the criteria for GD and are good candidates for SRS.

Transwoman A person who was born male but whose gender identity is female.

World Professional Association for Transgender Health (WPATH) International, multidisciplinary, professional association whose mission is to promote evidence based care, education, research, advocacy, public policy, and respect in transsexual and transgender health.

History of Transwomen Surgery

The development of modern gender reassignment surgery began in the twentieth century when, following rapid advances in the fields of endocrinology and plastic surgery after World War II, comprehensive medical and surgical treatments for transsexualism started to become available. In 1952, the Danish plastic surgeon Paul Fogh-Andersen initiated the modern era of sex reassignment surgery by using penile skin as a full thickness graft to line the neovagina of Christine Jørgenson ([Fogh-Andersen, 1956](#)). In the United States, things began to change during the late 1950s, when several hundred transsexuals came under the care of Dr. Harry Benjamin, a compassionate endocrinologist who was the first physician to elucidate the nature of gender dysphoria ([Benjamin, 1964](#)).

For the majority of transsexuals seeking surgery, the 'Clinique du Parc' in Casablanca was the place of last resort. There, Dr. Georges Burou (1910–1987), a French gynecologist, invented and applied the anteriorly pedicled penile skin flap inversion technique in 1956 ([Hage et al., 2007](#)).

In 1966, surgeons at the Johns Hopkins Medical Center began performing a limited number of Male-to-Female (MtF) sex reassignment surgeries (SRS) at its new gender identity clinic. Shortly thereafter, hospitals at Stanford, Chicago and Colorado followed suit ([Laub and Fisk, 1974](#); [Pandya and Stuteville, 1973](#)).

The surgeons at Johns Hopkins initially used partial thickness skin grafts to line the neovaginal cavity, but later used penile skin, applied as a full thickness skin graft, much as the technique employed in Copenhagen. The *posteriorly* pedicled penile skin flap

inversion technique for vaginoplasty — a variation of Burou’s method — was introduced by Edgerton and Bull at Johns Hopkins between 1968 and 1970 (Edgerton and Bull, 1970). Beginning in 1967, the Chicago group used the *anteriorly* pedicled penile skin flap to line the vagina, and scrotal skin to form the labia (Pandya and Stuteville, 1973).

In Europe, beginning in the 1970s, the University Hospital of the Free University of Amsterdam became the leading center for medical and surgical treatment of patients with severe gender dysphoria. By the end of the 20th century many centers of excellence employed a multidisciplinary approach for transsexual individuals, providing state of the art treatment, including surgical therapy, for both transwomen and transmen. With the recent increase in number of individuals seeking treatment for gender dysphoria, the quantity and the quality of the multidisciplinary teams has substantially increased worldwide with the largest number of vaginoplasties probably still being performed in Thailand.

Criteria for Male-to-Female Gender Reassignment Surgery

Standards of Care for Surgery

The 7th version of Standards of Care (SOC) of the World Professional Association of Transgender Health (WPATH) offers flexible guidelines for the treatment of people experiencing gender dysphoria and put forth the following criteria for surgical treatments (Coleman et al., 2012):

- For breast augmentation with implants or lipofilling (one referral):
 - Persistent, well documented gender dysphoria
 - Capacity to make a fully informed decision and to give consent for treatment
 - Age of majority in a given country
 - If significant medical or mental health concerns are present, they must be well controlled

Although not an explicit criterion, it is recommended that transwomen undergo feminizing hormone therapy (minimum 12 months) prior to breast augmentation surgery. The purpose is to maximize breast growth in order to obtain better surgical (aesthetic) results.

- For genital surgery, two referrals are recommended and specifically for orchiectomy the following criterion is added to the list above:
 - Twelve continuous months of hormone therapy as appropriate to the patient’s gender goals (unless hormones are not clinically indicated for the individual). The aim of hormone therapy prior to gonadectomy is primarily to introduce a period of reversible testosterone suppression, before a patient undergoes irreversible surgical intervention.
- For vaginoplasty one additional criterion is recommended:
 - Twelve continuous months of living in a gender role that is congruent with their gender identity (formerly called ‘real-life experience’).

Typically, the patient is advised to stop all hormonal therapy at least 2 weeks prior to any surgical procedure. Estrogens, in particular, can cause an increased risk of thromboembolic complications.

Facial Feminization Surgery and Voice Surgery

Facial Feminization Surgery

In most human interactions, the face communicates vital social information. First impressions are largely based upon a person’s facial features and expressions. A face reflects aspects of one’s personality and emotions, and serves as a vehicle to convey verbal and nonverbal communication. The head and face are commonly considered to be the location of the ‘self’. In initial contacts, it is most often the face that provides the clues about the person, including gender. For the transsexual patient, nothing is more important than to appear externally congruent with the internal and emotional self. While many patients undergo surgery to feminize the face, there is a paucity of literature on these procedures (Hage et al., 1997).

Forehead

Spiegel investigated the determinants of female gender and discovered a strong association between facial femininity and attractiveness more specifically attributed to the upper third of the face and the interplay of the glabellar prominence of the forehead, along with the eyebrow shape and position and the hairline shape and position. Based on differences in anthropological measurements, the size of the frontal sinus (in the mid-lower forehead above the eyes and nose) and the general contour of the orbits and forehead, three different ways of modifying the forehead shape have been developed. These vary from simple bony contouring to the more complex procedure, wherein the anterior wall of the frontal sinus is placed into a more posterior position, or in combination with filling of the concavity superior to the frontal bossing with bone cement. Orbital rim contouring may be helpful to make the orbit look bigger, and is completed at the same time. If indicated, a bilateral brow-lift can be simultaneously performed. The female brow is not positioned at the level of the supraorbital rim but just a little above. The female eyebrow has an arch shape with the highest point at one-third laterally in contrast with the male brow that is straight. Scalp

advancement can reduce the distance from the brows to the hairline, which is on average 5 cm for women, in comparison to 7 cm for men.

Cheeks

The cheekbones are more prominent in women and malar augmentation makes the face more heart-shaped. Cheek augmentation is therefore often effective in feminizing the face. Usually this is done with an implant or with soft tissue filling, but certain bone cuts (zygoma osteotomies) and bone segment repositioning may be useful in some cases. The bilateral partial removal of the buccal fat pads of Bichat at the same time can help accentuating the cheekbones by creating a sub-malar hollowing.

Nose

The nose is a feature that varies tremendously from individual to individual, and may be quite masculine appearing. The noses of men are usually larger than those of women and naso-labial and naso-glabellar angles are sharper. Contour changing alone greatly feminizes the basic nasal appearance. In a reduction rhinoplasty mostly dorsum and tip will have to be made smaller and the tip needs to be lifted and refined. The volume of the nostrils can be reduced by alar base excision. Correction of the frontal bossing and tip lifting make the naso-glabellar angle and naso-labial angle more obtuse and more feminine.

Chin

While the male chin is generally wide and vertically high, the female chin tends to be more pointed, narrow, and vertically shorter. The chin can be modified in numerous ways to improve facial appearance and feminize the lower face. This may only require a small implant or little shaving, but it is often necessary to perform extensive bone cuts, with removal of excess of bone and repositioning of the chin to make the chin shorter and narrower.

Angle of the mandible

Males tend to have a more obvious mandible angle, with thicker muscles and resulting fullness, than females. The female tends to have a smaller muscle with a more gradual curve or even a straight line along the lateral border from the posterior border of the mandible to the chin. A lower jaw contouring procedure is completed under general anesthesia through incisions in the mouth. The masseter muscle is reduced on its internal surface, i.e., the portion adjacent to the bone. The bone is then significantly reduced laterally, softening the bony angle. When there is a significant mandibular angle present, the angle is osteotomized to give this area a more rounded and smoother appearance. Botulin toxin can also be used to decrease the volume of the masseter muscle.

Upper lip

Lip lift is regularly used in facial feminization. Its aim is to shorten the upper lip in the area between the alar bases of the nose making the maxillary tooth crowns more visible. Also techniques making the upper lip more voluminous can help in making the face look more feminine. This can be done by fillers, but the use of dermis grafts, harvested from the coronal flap, has few complications.

Orthognatic surgery

Using the Le Fort 1 and bilateral sagittal ramus osteotomy a combination of feminizing effects can be obtained. A clockwise rotation of the bimaxillary complex with posterior impaction of the maxilla gives more volume to the midface making the face look rounder. It also makes the gonial angles more obtuse, makes the chin less pronounced and gives more show to the maxillary tooth crowns.

Hair transplantation

Hair transplantation, or scalp shifting, is very helpful in transwomen who have considerable balding. There are many ways to approximate a female hair pattern. Major procedures like scalp flap or tissue expansion may be required in some cases but, more often, plugs or micro grafts are employed. Scalp reductions are useful in certain individuals. For those with extensive baldness, there is no choice but to use a hairpiece.

Chondrolaryngoplasty and Voice Surgery

The secondary sex characteristics of the larynx with its vocal function remain a major obstacle to achieving gender congruency for many. Estrogen does not have any substantial or lasting influence on voice pitch, and speech therapy alone often does not produce satisfactory results.

Various authors have described operative techniques to raise voice pitch. Basically, this can be achieved by reducing the vibrating vocal cord length (shortening the vocal cords) or increasing the vocal cord tension. The most frequently used technique is the one described by Isshiki (1989). In this technique, the cricoid cartilage is approximated to the lower edge of the thyroid cartilage, causing an increase in vocal cord tension. The cricoid and thyroid cartilages are then fixed to each other with sutures. Nowadays, endoscopic surgery directly on the vocal cords is often performed.

A reduction of the prominent thyroid cartilage can be performed in the same procedure. During this intervention, the thyroid cartilage is exposed, perichondrial flaps are raised, and a resection of the upper limit of the thyroid cartilage is performed. According

to literature, surgical outcomes of voice pitch raising are very good, and the cosmetic benefit of the reduction of the Adam's apple contributes greatly to the patient's psychological wellbeing (Wolfort et al., 1990).

Breast Augmentation

For most transwomen, breast augmentation (or breast "reconstruction") greatly increases subjective feelings of femininity. In a prospective, non-comparative, cohort study it has been shown that the gains in breast satisfaction, psychosocial well-being, and sexual well-being after transwomen undergoing breast augmentation are statistically significant and clinically meaningful to the patient short after surgery as well as in the long term (Weigert et al., 2013). The augmentation mammoplasty may be performed at the same time as genital surgery, or as a preliminary or subsequent procedure.

Breast Development after Hormonal Therapy

While some breast formation occurs after hormonal therapy, for many, it is insufficient. Unfortunately there are no studies looking in detail on what is the optimum delay after start of hormonal treatment. The current version of the SOC does not explicitly indicate a minimum period of hormone therapy that must be completed before breast surgery may be performed. However, most surgeons recommend a 12 month period of feminizing hormone therapy prior to breast augmentation surgery in order to maximize breast growth and obtain better surgical (aesthetic) results.

Surgical Techniques

Since breast prostheses are implanted in transsexuals with "young adolescent" breast development, the patient should be informed that the complex feminine form and age-related changes of the breast cannot be imitated by using symmetric hemispherical prostheses. Therefore, the result of an augmentation mammoplasty in a transwomen with minimal hormone-induced mammogenesis may be poor (Kanhai et al., 1999a, b).

Other anatomical differences, which should be taken into consideration in transwomen, are (1) the wider male chest; (2) a stronger pectoral fascia and a more developed pectoralis muscle; and (3) a smaller dimension of nipple and areola. Usually a larger volume of breast prostheses is chosen by transwomen than that chosen for breast augmentation by a female patient, but even with a larger prosthesis, it is often impossible to avoid an abnormally wide cleavage between the breasts. The nipple areola should always overlie the prosthesis centrally and a very medial position of these prostheses could result in a divergent nipple position with an unacceptable breast appearance (Laub and Fisk, 1974) (Figs. 1 and 2).

In our personal experience we have used lipofilling as an adjunct to make the prosthesis less visible and palpable, as well as to narrow the wide cleavage between the breasts. In transwomen who already have some breast volume due to hormone treatment, lipofilling can be a good option to provide a moderate augmentation of the breast, therefore avoiding the need for an implant (Fig. 3).

Despite some sexual differences in chest wall and mammary anatomy, the implantation of mammary prostheses is not essentially different from breast augmentation in a female patient, except that, usually, larger prostheses are used. The same choices apply as to the kind of prostheses, the position of the pocket, the surgical approach, etc. Patient and surgeon can choose between a silicone gel-filled prosthesis and a saline filled prosthesis. In most cases, a textured prosthesis is chosen to reduce the chance of capsular contraction. When a more cohesive gel-filled prosthesis is chosen, it can be a round prosthesis or a so-called anatomical prosthesis, resulting in additional filling of prominence in the lower part of breast.

Fig. 1 Breast augmentation preoperative view.

Fig. 2 Breast augmentation postoperative view.

Fig. 3 Lipofilling was used for breast augmentation.

The incision can be made axillary, inframammary, or even periareolar, although the latter is less popular in transwomen because of the smaller size of the areola. If an inframammary incision is used, it should be positioned lower than the preoperative inframammary fold, as the distance between the inferior areolar margin and the inframammary fold will expand after augmentation mammoplasty, likely due to the recruitment of the inframammary or even abdominal skin ([Kanhai et al., 1999a](#)).

The pocket for the prosthesis can be created behind the glandular tissue or behind the pectoralis muscle. Some authors ([Kanhai et al., 1999a](#)) recommend implanting the prostheses in a subglandular position. This is especially indicated in patients who have more subcutaneous and glandular tissue to start with (Tanner Stage IV or V). The surgical procedure is easier to perform and less painful. Many surgeons, however, prefer to put the prostheses in a retropectoral position. In this case, the lower portion (as well as part of the medial origin) of the pectoralis muscle should be detached from the thoracic cage ([Monstrey et al., 2001](#)). In the retropectoral position, the prosthesis is covered with more soft tissue (important in case of thin patients), and a lower risk of capsular contraction has also been reported.

Complications

[Kanhai et al. \(1999b\)](#) reported the main (but rarely occurring) complications after breast augmentation: hematoma, symmastia, capsular contracture, a decreased sensation in the nipple and/or part of the breast, leakage of the prostheses (more obvious in

saline-filled prostheses than in cohesive silicone gel-filled prostheses), and malposition of the prostheses. Although it is very rare in these patients, mastopexy can be the treatment of choice to correct (substantial) mammary ptosis, but usually an augmentation is sufficient to fill out the (slightly) ptotic breasts.

Postoperative follow-up is mandatory in all patients undergoing breast augmentation. Gooren et al. performed a cohort study documenting the occurrence of breast cancer in 2307 transgender persons (Gooren et al., 2013). His study suggested that cross-sex hormone administration does not increase the risk of breast cancer development in transwomen. Breast carcinoma incidences were comparable to male breast cancers, and thus lower than in the female population. However, the historical use of cross-sex hormones may have been too short for malignancies to develop. Therefore good screening and follow up is imperative. Moreover, since breast exams are also very well accepted by transwomen, transgender persons should be encouraged to participate in relevant cancer screening protocols, which for breast cancer screening are the same as for cisgender women (Weyers et al., 2010).

Routine preoperative investigation of family history is imperative. Screening for genetic predisposition (such as BRCA mutations) should be considered in patients with multiple breast and/or ovarian cancers within their family (often diagnosed at an early age); two or more primary breast and/or ovarian cancers in a single family member and/or cases of male breast cancer within their family. Psychological counseling about bilateral prophylactic mastectomy and consecutively primary reconstruction with either autologous tissue (such as a deep inferior epigastric perforator (DIEP) flap) or prosthesis should be offered in patients with a genetic predisposition of breast cancer (Colebunders et al., 2014).

Orchiectomy

An orchiectomy can be performed simultaneously with a vaginoplasty or as a first stage procedure prior to the vaginal reconstruction. If an orchiectomy is performed as a preliminary procedure, it will not compromise the possibility of a vaginoplasty at a later stage, as the testicles can be accessed via a short 5 cm incision at the raphe leaving very little scar tissue. Androgen-blocking treatment can usually be stopped or reduced after the orchiectomy.

Reproductive Options

Attention should be given to reproductive possibilities and restrictions after orchiectomy. A majority of transwomen has been reported to desire to have children (Wierckx et al., 2012). Transwomen should be given the option of sperm preservation in sperm banks, prior to initiating hormones.

Vaginoplasty

As affirmed by Karim et al. (1996), the goal of genital reassignment surgery in male-to-female transsexuals is to create a perineo-genital complex as feminine in appearance and function as possible and free of poorly healed areas, scars, and neuromas. The urethra should be shortened in such a way that the direction of the urinary stream is downward in the sitting position and it should be free of stenosis or fistulas. The neovagina should, ideally, be lined with moist, elastic, and hairless epithelium. Its depth should be at least 10 cm and its diameter 30 mm. The sensation should be sufficient to provide satisfactory erogenous stimulus during sexual intercourse.

The major steps in a vaginoplasty are an orchiectomy (if not previously performed), amputation of the penis, creation of the neovaginal cavity, the lining of this cavity, reconstruction of a urethral meatus and, finally, construction of the labia and clitoris.

In order to obtain a functional and aesthetic outcome, most authors advise to construct a wide and deep vaginal cavity, to perform a near-complete resection of the corpus spongiosum, an eversion of the urethral mucosa and the construction of clitoris/clitoral prepuce, labia minora/majora. Several refinements of vaginoplasty (mostly using the inverted penile-scrotal skin flap technique in combination with skin grafts) have been described (Karim et al., 1995; Selvaggi et al., 2005). These include (1) preoperative epilation of the area at the base of the penis and posterior scrotum; (2) preoperative bowel preparation; (3) the use of a drape with a rectal condom; (4) blunt dissection of the vaginal cavity; and (5) the use of double silicone prosthesis to create and maintain a vaginal cavity of adequate dimension.

Vaginal Lining

Methods for lining the neovagina can be classified into six categories: (1) non-genital skin grafts; (2) penile or scrotal skin grafts; (3) penile-scrotal skin flaps; (4) non-genital skin flaps; (5) pedicled intestinal transplants and (6) recent developments.

Nongenital skin grafts

Laub and Fisk reported the first series of transwomen in whom a split skin graft pulled over a plastic mold was applied in a one-stage vaginoplasty (Laub and Fisk, 1974). The use of a full-thickness skin graft, harvested from the region of a (mini) abdominoplasty, has been described by Hage and Karim (Hage and Karim, 1998). Because of disadvantages like the tendency of the skin graft to shrink

(postoperative daily dilation is required), suboptimal sensation, and the absence of any natural lubrication (McGregor, 1989) it is not used as single reconstructive option.

Penile or scrotal skin as graft

Fogh-Andersen was the first to report the use of a full-thickness skin graft harvested from the penile skin to line the neovagina (Fogh-Andersen, 1956). However the use of penile skin as a graft for vaginoplasty is rarely, if ever, performed as it is usually preserved to be used as a (pedicled) penile flap undergoing less contraction postoperatively.

Penile–scrotal skin flaps

This is the technique of choice. As previously discussed, Burou has been credited with inventing the anteriorly pedicled penile skin flap inversion technique, and it became (and still is) the technique of choice for vaginoplasty in transwomen. However, in 1957, Gillies was the first to report on the use of penile skin as a pedicled flap for vaginoplasty (Gillies and Millard, 1957). Several modifications of this technique were subsequently described. These can be classified into the following three groups (Bouman, 1988):

1. The inverted penile skin is used solely on an abdominal pedicle as an inside-out skin tube (Gillies and Millard, 1957; Eicher, 1989); this penile skin flap can be augmented with a small triangular scrotal skin flap to “break” the circular introitus (Bouman, 1988; Karim et al., 1995). Variations of this technique are used by most surgeons who perform sex reassignment surgery in transwomen today and this technique is therefore considered “the gold standard in vaginoplasty” (Figs. 4, 5, and 6).
2. The pedicled penile skin tube can also be split open to form a rectangular flap which is augmented by a rectangular, posteriorly pedicled scrotal skin flap comparable in size (Jones et al., 1968).
3. The inverted penile skin tube may be applied based on an inferior pedicle (Edgerton and Bull, 1970). Perovic et al. described a modification of the technique wherein a long, vascularized urethral flap is harvested and embedded in the penile skin tube flap (Perovic et al., 2000). They also described the suspension of the neovagina to the sacrospinous ligament to prevent vaginal prolapse, a complication that is rarely, if ever, experienced by others.

There are several advantages to penile skin flaps. They demonstrate fewer tendencies to contract (McGregor, 1989). In the event of inadvertent damage to the rectum, correction is easier, as it is immediately covered with vascularized tissue (Karim et al., 1995). Local innervation is provided and the flap is virtually hairless. Although flaps have much less tendency to contract than grafts, patients are still required to use a dilator postoperatively for 6 months. The disadvantages of penile skin flaps are that a limited amount of penile skin may be available (van Noort and Nicolai, 1993), and that this technique might result in widening of the anterior commissure, which can leave the clitoris more exposed (Karim et al., 1995; Bouman, 1988).

Combining an abdominally pedicled penile skin flap with a wide posteriorly based scrotal skin flap produces an ideal anatomically located introitus and favorable dimensions of the neovagina (van Noort and Nicolai, 1993). However, this technique will introduce hair-bearing scrotal skin within the posterior lining of the vagina if the epilation has not been performed prior to surgery (Figs. 7 and 8).

Fig. 4 Inverted penile skin flap technique with dorsal scrotal flap.

Fig. 5 Inverted penile skin flap technique after resection of all erectile tissue.

Fig. 6 Inverted penile skin flap technique.

Nongenital skin flaps

In 1980, Cairns and De Villiers reported the use of a medial thigh flap for vaginoplasties in four patients who had previously undergone penile skin inversion vaginoplasty with inadequate results (Cairns and de Villiers, 1980). Huang used two inguino-pudendal flaps, sutured to one another in the midline and then to the penile flap, forming a single large flap (Huang, 1995). The use of distant free flaps for vaginoplasties in transsexuals has never been reported.

The advantages of using non-genital flaps are that they have less risk of contraction and a reduced period of postoperative dilation. The disadvantages are donor site morbidity and scarring, technical complexity (in some cases the flaps are unreliable) (Wee and Joseph, 1989), and their tendency to be bulky as compared to genital skin flaps. This added bulk can decrease the functional dimensions of the neovagina, which is particularly disadvantageous in transwomen, as the male pubic arch is narrower than the female (Karim et al., 1996). Again, these flaps have no natural source of lubrication. Non-genital skin flaps should be reserved as a choice of last resort, after all other options have been exhausted.

Pedicled intestinal transfer

Intestinal vaginoplasty is a good alternative technique in cases where insufficient skin is available. A lack of penile and scrotal skin is often present in young transwomen who started hormonal therapy at an early age. Transwomen who had a previous

Fig. 7 Vaginoplasty: Early post-operative result (2 weeks) with still swollen smaller and greater labia.

Fig. 8 Vaginoplasty—result after 3 months.

failed vaginal reconstruction with skin flaps and/or grafts can also benefit from this procedure (Kim et al., 2003). A pedicled intestinal transfer can also be used to elongate the vagina in transwomen requiring more depth after a previous vaginal reconstruction.

Both small as well as large intestinal segments have been used for vaginal reconstruction (Bouman et al., 2014). For vaginoplasty with a large intestinal segment, the sigmoid is most commonly the first choice. In case the small intestines are used, the ileum is mainly chosen. Harvest of the bowel can be performed through a median or Pfannenstiel laparotomy,

a laparoscopy-assisted-laparotomy or totally laparoscopic. Laparoscopic harvest of bowel has been described by Wedler in 2004 and has been more widely used since (Wedler et al., 2004). Zhang et al. showed that laparoscopic-assisted vaginoplasty using pedicled ileum or sigmoid segment are both effective in reconstructing a vagina (Zhang et al., 2014).

The advantages of using a recto-sigmoid transplant are not only the length it provides, but also the texture and appearance which is more similar to vaginal lining and of course its natural lubrication (Dalton, 1981; Kim et al., 2003). Although the natural lubrication with the production of mucus is usually regarded as an advantage, it may lead to excessive discharge (Hage et al., 1997), especially when ileum is used, compared to colon.

Neovaginal length after an intestinal transfer usually is significantly longer compared to other vaginoplasty techniques. However, if the intestinal segment is taken too long, it can lead to stasis and dehydration of mucus in the deepest portion of the vagina. An intestinal transfer itself has little or no tendency to shrink but dilation remains important to avoid introital stenosis, which is the most common reported complication of intestinal vaginoplasty (Bouman et al., 2014).

Bouman et al. performed a review of the literature focusing on clinical outcomes of intestinal vaginoplasty including 21 studies (Bouman et al., 2014). Prevalence and severity of procedure-related complications were low. Diversion colitis (inflammation that occurs in the bypassed colonic tissue related to diversion of the fecal stream), was very rare. Severe complications were incidental and included necrosis of the intestinal segment, necrotizing fasciitis, bilateral lower extremity compartment syndrome, an intraluminal abscess and intestinal obstruction.

Recent developments

- Autologous buccal mucosa. In 2003 Lin et al. were the first to describe vaginoplasty with autologous buccal mucosa as graft material in eight cases of vaginal agenesis, such as Mayer-Rokitansky-Küster-Hauser syndrome (MRKHS) (Lin et al., 2003). Later, in 2014 Li et al. modified this technique by using micro grafts of the buccal mucosa, minimizing donor site morbidity and enlarging the possible surface area to be grafted (Li et al., 2014). Dessy et al. reduced donor site morbidity even further by taking a 2 cm² full thickness oral biopsy and culturing it into fully differentiated mucosal tissue (Dessy et al., 2014).
- Acellular dermal matrix. To date there are no reports using acellular dermal matrix as vaginal lining in transwomen. However its use has been described for vaginal reconstruction in patients with Mayer-Rokitansky-Küster-Hauser syndrome. Ding et al. reported successful use of acellular porcine small intestinal submucosa graft in MRKHS patients (Ding et al., 2015). In future it might become a choice for transsexual patients who have previously undergone penectomy and orchiectomy. Main drawback of using acellular dermal matrix, however, is the high cost.

Clitoro-labioplasty (Vulvoplasty)

In order to achieve the physiologic and aesthetic equivalent of female external genitalia it is imperative to create labia majora and minora, a clitoris and a clitoral hood. The creation of the labia majora is dependent on the use of either a penile flap or a graft, and the amount of scrotal skin remaining after resection. Secondary corrections may be needed and a common secondary correction is symmetrization of the labia majora and sometimes a commisuroplasty with recreation of the anterior commissure covering the neoclitoris (Selvaggi et al., 2005).

Little has been written specifically about the labia minora. Perovic et al. described using the base of the penile skin to form the labia minora, which are then sutured to the deepithelialized area of the neoclitoris. Thus, the neoclitoris is hooded with labia minora (Perovic et al., 2000). We have used penile foreskin (in continuity with the glans flap for clitoral reconstruction – see below) in order to construct the labia minora and the clitoral hood.

The first person to describe the construction of a neoclitoris was Brown, in 1976. He reported the creation of a functional clitoris using the reduced glans, which remained attached to its dorsal penile neurovascular pedicle (Brown, 1976, 1978). At present, most surgeons performing a clitoroplasty in transsexual patients use the dorsal portion of the glans penis in a horseshoe or W-pattern with the dorsal neurovascular pedicle (Selvaggi et al., 2005; Karim et al., 1995). Dissection of the pedicle can be performed in a plane just above the tunica albuginea of the corpora cavernosa, or in a plane just posterior to this tunica. The latter is a more rapid dissection, but may result in a bulky pedicle and thus an elevated mons pubis.

The clitoral hood and the labia minora can be constructed using a thin inner layer of penile foreskin, which is harvested in continuity with the glans flap. This is the only manner in which the very delicate features of the anterior commissure of the vulva, where the clitoris is located and where the labia minora start from the clitoral hood, can be reconstructed in a natural way (Figs. 9 and 10).

The neoclitoris has the ability to swell and cause a climax on erogenous stimulation. In order to achieve swelling of the labia minora as well, we have designed an extended clitoroplasty in which two lateral extensions of the glans penis are placed in the base of the labia minora (unpublished data). Anatomically, this extended neoclitoris mimics better the female clitoral apparatus. The extensions simulate the female corpora cavernosa; cylindrical organs, made of cavernous erectile tissue who are the “hidden” part of the clitoris (Puppo, 2011).

Selvaggi et al. (2005) described the use of the penile urethra to construct the region between the urethral opening and the neoclitoris. The urethra is incised longitudinally along its ventral aspect, folded open, and sutured just inferior to the neoclitoris. This produces a natural appearance, in both color and texture (Fig. 11).

Fig. 10 Long-term result vagino-clitoroplasty.

Postoperative Care

When an anteriorly pedicled penile skin flap technique has been used in combination with a posterior scrotal flap and skin grafts, the patient usually remains in bed for 4–5 days, with the dilator firmly in place. Fractionized Heparin is provided subcutaneously.

After 5 days, the dilator is removed, and the patient is allowed to ambulate. The neovaginal cavity is cleansed daily with an iso-betadine solution and the patients starts to dilate according to a strict protocol. The following day, the urethral catheter is removed and spontaneous voiding is started.

Fig. 11 Long-term result vagino-clitoroplasty: labia minora and clitoris.

The patient is usually discharged on the seventh or eighth postoperative day, and is instructed in the care of the neovagina. This consists of progressive removal of the dilator and irrigation of the vaginal cavity with isobetadine. The period of time that the dilator remains out is gradually increased over the following 3–6 months. Later, if the patient is having regular sexual intercourse, no further dilation is required. Otherwise, routine dilation should continue once or twice per week, especially if a full-thickness skin graft has been used in addition to the pedicled penile skin flap.

Complications

Although the surgical techniques for vaginoplasty have evolved and improved significantly, the patients have to be informed that both medical and surgical treatments are rarely perfect. Revisional surgery is sometimes required to optimize aesthetic results.

Early (but rare) postoperative complications include bleeding (usually resolved by applying some pressure), lower extremity compartment syndrome, infection or impaired wound healing. One specific complication related to the vaginoplasty procedure is the development of a recto-vaginal fistula, as the vaginal cavity needs to be created between the prostate urethra anteriorly and the rectum posteriorly. The rectum has a rather thin wall, and care must be taken to avoid a perforation. If a rectal injury occurs during the dissection of the neovagina, a double layer closure should be performed. This usually heals without problem since a preoperative bowel preparation is routinely performed.

Possible late complications include stenosis of the new urethral meatus, which is rare with the eversion flap of the urethral mucosa.

Life-long vaginal hygiene and dilatation is recommended, especially in operated transwomen undergoing limited or no penetrative sex. Most patients are able to reach an orgasm after the operation (clitoral in most cases), and despite the fact that they often experience some moistening of the vulva during sexual excitation most transwomen require lubrication for sexual intercourse. Until the first uterine transplantation in a transwoman, pregnancy is of course not possible.

Glossary

Assisted reproductive technology (ART) All treatments or procedures that include the in vitro handling of both human oocytes and sperm or of embryos for the purpose of establishing a pregnancy. This includes, but is not limited to, in vitro fertilization and embryo transfer, gamete intrafallopian transfer, zygote intrafallopian transfer, tubal embryo transfer, gamete and embryo cryopreservation, oocyte and embryo donation, and gestational surrogacy. ART does not include assisted insemination (artificial insemination) using sperm from either a woman's partner or a sperm donor.

Elective embryo transfer The transfer of one or more embryos, selected from a larger cohort of available embryos.

Embryo The product of the division of the zygote to the end of the embryonic stage, 8 weeks after fertilization. (This definition does not include either parthenotes—generated through parthenogenesis—nor products of somatic cell nuclear transfer.)

Embryo donation The transfer of an embryo resulting from gametes (spermatozoa and oocytes) that did not originate from the recipient and her partner.

Implantation rate The number of gestational sacs observed divided by the number of embryos transferred.

In vitro fertilization (IVF) An ART procedure that involves extracorporeal fertilization.

Infertility (clinical definition) Disease of the reproductive system defined by the failure to achieve a clinical pregnancy after 12 months or more of regular unprotected sexual intercourse.

Initiated cycle An ART cycle in which the woman receives specific medication for ovarian stimulation, or monitoring in the case of natural cycles, with the intention to treat, irrespective of whether or not follicular aspiration is attempted.

Ovulation induction (OI) Pharmacologic treatment of women with anovulation or oligo-ovulation with the intention of inducing normal ovulatory cycles.

Abbreviations

ACTH Adrenocorticotropin hormone

CRH Corticotropin releasing hormone

GnRH Gonadotropin-releasing hormone

LH Luteinizing hormone

Psychological Intervention in a Reproduction Treatment

According to the World Health Organization, infertility is a disease of the reproductive system defined by the failure to achieve a clinical pregnancy after 12 months or more of regular unprotected sexual intercourse (Zegers-Hochschild et al., 2009). Nearly two decades after the inclusion of psychology in the multidisciplinary teams of AR centers, it is a known fact that in general, the difficulties to conceive may have profound psychological effects and are often accompanied by an evolutionary crisis. This crisis is the reflection of internal conflicts in which stress (referred as distress), anxiety, excessive sadness and depression are manifested (Guerra, 2002).

The search for solutions to getting pregnant usually leads to emotional suffering, which would be more or less intense due to multiple personal and situational factors. Currently we know that between 25% and 65% of patients undergoing an AR treatment display clinical symptoms of stress, anxiety and negative emotions such as hopelessness, low self-esteem or guilt (Guerra, 2002; Guerra et al., 1998).

Accepting the infertility diagnosis can create a vital crisis in both the diagnosed person and in her partner. It is an emotional imbalance produced by a problem for which almost no one is prepared for. Occasionally this suffering is carried in secret, which in turn produces social isolation. This diagnosis implies entering a medical world that they do not know of, with lots of clinical tests,

medications and even surgical interventions that, although not compromising life, it will never be the same. All this combined with the uncertainty of success or failure of the treatment makes one of the most important projects of human beings “stagger” (Hill et al., 2016).

Over the years, the relationship between psychological aspects and infertility has become more and more evident. In some cases, patients can become more anxious, increasing sexual dysfunction (Bracewell-Milnes et al., 2016; Cousineau and Domar, 2007). For years, distress has been recognized among the scientific community as a risk factor associated with infertility because of its more than likely negative influence on reproductive success, probably decreasing the pregnancy rates. This is possibly due to both the sustained stress that people suffer in their daily lives for work or family reasons and the stress that is generated when feeling infertile and becoming an AR patient.

For all of the above reasons, nowadays there is a consensus regarding the comprehensive care of assisted reproduction patients, including the emotional and psychological support from the outset to reduce the levels of stress, anxiety and depression among patients undergoing treatment (Blyth, 2012; Peterson et al., 2012). It has been highlighted that women trying to get pregnant and couples facing IVF treatments often have depression rates similar to women who have cancer (Domar et al., 1993).

The psychologist in the field of AR, and indeed in all areas, is a process facilitator who helps patients, making their relationship with reality more positive. At the beginning of AR treatments, we will find couples with affectionation in different areas. The psychologists can identify problems at the cognitive level, when the ability to face problems and the problem solving skills usually used are overwhelming. Also frequent are the affections at the psychological level, reflecting feelings of denial, confusion, fear, sadness, emotional flattening, disbelief, guilt, excitability and restlessness follow the initial state of shock. In addition, it is common to find a general stress reaction caused by affections at the physiological level (Gameiro et al., 2015).

On the other hand, the medical treatment itself and its vicissitudes are often the source of emotional alterations. If any medical treatment is a source of stress for the patient, the assisted reproduction treatment is especially so. In fact, we can summarize this affectionation in a high percentage of the patients in AR treatment as an adaptive disorder which brings with it anxiety, distress, sadness, and depression.

The approach of patients by the psychology unit follows a protocol within the competencies of the psychologist in an AR center (Guerra, 2002). In our center, we follow a program implemented with the aim of integrating patient-centered attention into the daily activities of the medical team and, at the same time, making use of counseling and psychological intervention to meet any exceptional patient need.

This developed program consists of several actuation areas. The psychological unit offers the possibility of having an initial interview and psychological advice to all those persons or couples who desire it: advice to all couples or single female recipients; advice to all couples after pregnancy (especially multiple pregnancies); council to all embryo reductions and curettages; advice to patients who have to complete their treatment; treatment by cognitive-behavioral intervention of diagnosed disorders or symptomatology; derivation to the psychiatrist in the case of serious pathology consideration and therapeutic groups, for the prevention of possible emotional difficulties through information and teaching strategies to face problems, trying to stimulate psychological support among patients.

For a good psychological intervention, in all the steps of the infertility consulting is very important the training of the professionals that will have contact with the patients (as receptionists, secretaries, nurses, embryologists, and physicians). This training consists of patient care, crisis management, group dynamics, communication skills, and “burn-out” syndrome.

All this training has to be supervised by the expert in emotional support, providing skills in human resources, as support in the personnel selection process, resources and job optimization, group invigoration and emotional support to the team. These tools can be enforced by training courses for mental health professionals.

Finally, there has to be a feedback to evaluate this attention, through a systematic evaluation of the patients satisfaction regarding emotional support by the team, through questionnaires of perceived satisfaction.

The second area is referred to the psychological intervention itself. A systematic evaluation of possible risk populations within the group of patients by the development of screening tools (with a high cut-off point) has to be performed, for the detection of possible pathology. In the first visits or patients that start a new cycle and were not evaluated previously, nurses will give a test to the couple and the results will be evaluated by the psychologist. Couples and single women who choose donated gametes or embryos, will also be provided with advice for “reproduction with a Third Party”. Special psychological interviews will be performed to “reproductively older women” (women older than 40 years old) and gamete and embryo donors. Any patient that requests her evaluation will have it.

This psychological help is focus in facilitate the expression of emotions, identify the causes of emotional difficulty, educate about infertility, being sure that they have the necessary information in order to make decisions about the treatments to which they will undergo, and minimizing distress and equip patients with coping strategies for better adherence to treatments.

To achieve these goals, apart from this patient-centered care and psychological intervention, patients have a psychological support program based on “Brief Behavioral Cognitive Therapy”, in which patients are evaluated and trained in emotional self-control techniques and coping strategies. Some of the evaluation tools used are described above (Table 1).

Psychological Factors Associated to IVF Treatments

Since the development of the in vitro fertilization (IVF) procedure in 1978, there has been growing interest in the emotional experiences of IVF patients. Patients frequently report infertility and its treatment as one of the most stressful experiences of their lives.

Table 1 Evaluation tools

<i>Evaluation tool name</i>	<i>Objective</i>	<i>Characteristics</i>
Fertility quality of life tool (FertiQoL)	To evaluate the influence of infertility problems in different areas of life, such as the impact on self-esteem, emotions, general health, family, the couple, social relationships, work life, future life projects and the emotional impact of assisted reproduction treatments	Self-reported questionnaire, completed by the patients. (Boivin et al., 2011b)
The State–Trait Anxiety Inventory (STAI)	Measure of trait and state anxiety. Used to diagnose anxiety and to distinguish it from depressive syndromes	Self-reported questionnaire (Spielberger et al., 1983)
The Infertility Self-Efficacy Scale (ISES)	To measure the perception of self-efficacy in people facing infertility treatments	(Cousineau et al., 2006)
The Beck Anxiety Inventory (BAI)	To measure the severity of anxiety in children and adults	Multiple-choice self-report inventory (Beck et al., 1988)
State–Trait Anger Expression Inventory 2 (STAXI-2)	To assess state anger, trait anger, and anger expression and to measure the way these components contribute to medical conditions	(Forgays et al., 1998)

Among the undesirable effects of stress on health, there exists evidence that it adversely affects reproductive function (Rockliff et al., 2014).

Currently, lots of psychological factors have been associated to the IVF treatment success and could be used to assist in the identification of prospective IVF patients at high risk of psychological distress (Rockliff et al., 2014). After the meta-analysis of Rockliff and colleagues, neuroticism and the use of escapist coping strategies were linked with increased distress by multiple studies. Neuroticism, also known inversely as “emotional stability”, refers to the tendency to experience negative emotions. Neuroticism personality may experience primarily one specific negative feeling such as anxiety, anger, or depression. Social support was associated with low distress levels across several studies. A few other psychosocial variables, including self-criticism, dependency, situation appraisals and attachment style, appear to be associated with distress but have only been explored by one or two studies at most (Rockliff et al., 2014).

Classically, stress is defined as any physical or psychological stimulus that disturbs individual homeostasis. It can be understood as a condition in which the individual is alerted by an unfavorable situation. However, the concept of stress is more complex, so its interpretation requires some important considerations. First, for a situation to be considered stressful for an individual, that person must perceive it as an alarming or unusual experience. However, this first requirement may also be a component of pleasurable experiences. It is known as eustress, or simply stress, to “the good” stress, to that stress that helps us to be aware of ourselves, to leave our comfort zone and to run certain risks that are not dangerous, but help us to improve our personal development and grow (Witt et al., 2009). On the other hand, it can be defined as distress the “unpleasant” stress. It is a stress that causes an excess of effort in relation to the load or threat. It is always accompanied by a physiological disorder. It is understood as a set of harmful stimuli that weaken, subtracts confidence in oneself and subtracts strength to act. This second condition refers to the individual considering the circumstance in a hostile manner and, therefore, trying to modify or avoid that state. Distress represents the effects of anything that seriously threatens homeostasis. Stress-related outcomes also vary according to personal and environmental factors. Personal risk factors for the development of depression, anxiety, or posttraumatic stress disorder (PTSD) after a serious life event, disaster, or trauma include prior psychiatric history, neuroticism, female gender, and other sociodemographic variables. There is also some evidence that the relationship between personality and environmental adversity may be bidirectional. Levels of neuroticism, emotionality, and reactivity correlate with poor interpersonal relationships as well as “event proneness.” Protective factors that have been identified include, but are not limited to, coping, resources (e.g., social support, self-esteem, optimism), and finding meaning (Schneiderman et al., 2005).

The other component to take into consideration is the ability of the individual to control the stress situation. In this way, subjects able to maintain control during adverse experiences, manage to attenuate the detrimental consequences of stress to a greater extent than individuals who fail to react favorably to the same stimulus. The magnitude of the stress response with its consequent physiological effects will be greatly affected by the individual’s perception and ability to control the situation. The stress response involves physiological and psychological processes that are normally activated in new or adverse situations. Therefore, this response is an advantage for the healthy organism, which allows to adapt and overcome the unfavorable conditions.

Some previous studies in humans have concluded that emotional distress caused by fertility problems or other life events co-occurring with treatment will not compromise the chance of becoming pregnant (Boivin et al., 2011a). The controversy between studies has been related to the criteria to classify patients as distressed or controls, the design of the study, or small sample size (Smeenk et al., 2001).

In 2002, we performed one of the first projects that relate high scores on stress and anxiety with poor results of assisted reproduction treatments (Dolz and Garcia, 2002). This study aimed to verify if there is relation between counting or not on psychological support and a positive result of the assisted reproduction treatment (in terms of pregnancy). Two groups of assisted reproduction patients were compared. The first group was submitted to psychological support (35 patients) and the second one was not (25

patients). As follow-up criteria were considered the number of dropouts of the assisted reproduction treatment and the percentage of pregnancies in both groups. The psychological support program has a variable duration but on average consists of eight sessions given over 2–3 months. The program was based on four fundamental pillars. The first one was training in self-control techniques as breathing, relaxation, stopping negative thoughts, rejection and cognitive reconstruction of ideas and irrational beliefs. The second one was the induction of a positive emotional state (self-reinforcement, assertiveness, positive visualizations). The third one was training in prevention techniques and response control, reinforcing and scheduling critical stages along the treatment, and the fourth was to provide general information about the treatment, description of the steps to follow, desensitization about phobias or possible parallel problems that may arise.

The results obtained in this study were very interesting. In the group that followed the psychological support program, we obtained 54% of pregnancies, with a percentage of abandonment of the ART of 5.7%. However, in the group that did not follow the program, 28% pregnancies and live births were obtained with an abandonment rate of the ART 37.5% (Dolz and Garcia, 2002). As the results reflected, we considered that the patients that received psychological support during the ART cope better with the penalties and show less treatment abandon, due probably a higher quality of life and a better emotional situation. They are livelier to try it more times and therefore they have more probabilities to achieve their goal.

Physiological Mechanism Between Psychology and Infertility

The physiological mechanisms related to stress and reproduction are thought to include centrally controlled GnRH pulse inhibition as well as autonomic nervous system activation leading to alterations in ovarian and uterine function (Rockliff et al., 2014).

Stress hormones are produced by the sympathetic nervous system (SNS) and hypothalamic-pituitary adrenocortical axis. The SNS stimulates the adrenal medulla to produce catecholamines (e.g., epinephrine). In parallel, the paraventricular nucleus of the hypothalamus produces corticotropin releasing hormone (CRH), which in turn stimulates the pituitary to produce adrenocorticotropin (ACTH). Adrenocorticotropin then stimulates the adrenal cortex to secrete cortisol. Together, catecholamines and cortisol increase available sources of energy by promoting lipolysis and the conversion of glycogen into glucose (e.g., blood sugar).

The short term stress response can become maladaptive if it is repeatedly or continuously activated. Chronic SNS stimulation elevated basal levels of stress hormones associated with chronic stress also suppress immunity by directly affecting cytokine profiles. Cytokines are communicatory molecules produced primarily by immune cells involved in inflammatory reactions (Schneiderman et al., 2005).

It is well documented that the long-term stress can lead to serious depression, anxiety, eating disorders, irrational fears, stomach ulcers, irritable bowel syndrome, chronic migraines, blood pressure issues, heart problems, osteoporosis, hair loss, and hormonal imbalances and sexual dysfunction. Long-term untreated stress can lead to serious illness. Stress hormones alters the immune system and other tissues and systems as cardiovascular, digestive, musculoskeletal, reproductive and others as skin, hair, asthma attacks, dry mouth, and mouth ulcers.

Sensory stimuli are processed in the central nervous system through two pathways. The first is a direct and rapid pathway, whose reflex and stereotyped responses are carried out in the spinal cord and brain stem (neurovegetative responses to stress) or in the hypothalamus (neurohumoral responses). In the second route, sensory information is directed through multiple relays and projections to specific areas of the cerebral cortex, such as the primary visual area (area 17 of Brodmann), the auditory area (area 41) or the somatosensory area (areas 3, 1 and 2). These areas are responsible, through their connections with regions such as the hippocampus, the amygdala and the septal area, to modulate information on body activation and behavioral planning. It is precisely this evaluative process that gives the adaptive and plastic character to the response to stress.

Exposure to severe stress situations or for long periods of time can adversely affect the body by compromising the health of the individual and is what we call distress at the present work.

The molecular relationship between stress and reproductive physiology is obvious in the steroid hormones synthesis in adrenal cortex (Fig. 1). During the stress effect, glucocorticoids (cortisol) and mineralcorticoids (aldosterone) are also formed from progesterone. This fact is important because glucocorticoids production could alter progesterone, estrogen and androgens production as they derive from their metabolism. Likewise, key functions in embryo implantation as immune system, cytokines and energetic metabolism are compromised in stress response.

At the ovarian physiology level, it has been demonstrated in sheep that stress increases CRH, increasing ACTH and therefore increasing cortisol. On the other hand, it decreases the GnRH and LH pulse amplitude, delaying the LH peak, decreasing estradiol levels and, although follicle growing can be observed, maturation and ovulation is impaired, as they depend on quicker pulses. In case of lower stress and quicker pulses, granulosa cells integrity is affected, altering their connexion with the oocyte. In this case, progesterone receptors do not seem to be involved. Also if the LH pulse is inadequate, ovulation cannot occur and the follicle can persist provoking a cystic ovarian syndrome (Dobson and Smith, 2000).

The complex relationship between psychological factors and fertility stress begins to become more and more recognized in the scientific literature as a factor that on some occasions can negatively influence the reproductive capacity of human beings. Probably for what we know it can become a determining factor as a mediator in the case of at least 5% of sterility problems of unknown origin. However, more detailed molecular information of what is happening in ovary and endometrial function in humans still remains unclear. Due to all these reasons, systematic attempts have been made to determine the emotional difficulties experienced

Fig. 1 Molecular relationship between long-term stress effect and reproductive physiology. The hypothalamus hipofisiary axis is activated in long-term stress response. CRH activates ACTH that increases the cortisol and aldosterone production and secretion in adrenal cortex. Immune systems is one of the affected systems by glucocorticoids production that increases cytokines that activates CRH and ACTH.

by sterile couples. The understanding of these difficulties and their therapeutic approach, by the mental health professional, becomes pressing in the clinical context from a perspective of comprehensive vision of the care required by the patients.

In this same line, some studies show that higher levels of stress suffered by the ART patient are correlated with higher abandon rates (Freeman et al., 1987). However, research works that relate high levels of stress (distress) to infertility are still inconclusive. On one hand, some studies show a clear relationship between distress, anxiety and depression with infertility (Borghi et al., 2017; Karaca et al., 2016) but, on the other hand, some works conclude with no evidence of that relationship. Although we must add that there are more of those who conclude that there is a relationship of negative psychological aspects with implantation failures and ultimately with infertility.

Two studies, one performed in Europe and the other in United States, found association between stress and fertility. Buck Louis et al. found that stress significantly reduced the probability of conception each day during the fertile window, possibly exerting its effect through the sympathetic medullar pathway (Louis et al., 2011). In a prospective cohort study Lynch and colleagues found that preconception stress increased the risk of infertility. Data suggest that stress and reproduction are interrelated; however, the directionality of that association is unclear (Lynch et al., 2014). Both studies demonstrated a prospective association between salivary stress biomarkers and longer time to pregnancy, and Lynch et al., the first in the world to observe an association with infertility. In contrast, they found no association between salivary cortisol and fecundability as Buck Louis et al. in 2011 in European population (Louis et al., 2011). After these two studies the evidence to associate stress with infertility have been found due to measured alpha amylase to classify patients as distressed.

Systems Medicine and Psycho-Cognitive Aspects

The systems medicine approach is an information-based discipline focused on a holistic understanding of complex biomedical systems. This is based on the application of information technology to increasingly understand sets of clinical, molecular, cellular, phenotypic, demographic, and psycho-cognitive patient data (Fig. 2) (Hood and Friend, 2011). Nowadays, the systems medicine called P4 medicine (predictive, personalized, preventive and participatory) models to treat patients has been transformed into P5, including as fifth P the "Psycho-cognitive" aspects to be considered in order to empower the patient, increase his/her quality of life and transform him/her from a passive recipient into an active decision-maker. The fifth P analyzes the behavioral component on the

Fig. 2 P5 Systems Medicine Ecosystem. A schematic representation of the main actors involved in Systems P5 Medicine. EHR, Electronic Health Record.

way individuals act to prevent, cope and react to illnesses, how they decide between different therapeutic options and interact with clinicians in the treatment process (Gorini and Pravettoni, 2011).

All this patient information from a P5 medicine approach is a new way to perform medical practices and to develop smart health strategies providing personalized, safe and cost effective treatments (Flores et al., 2013).

This P5 medicine approach is an excellent opportunity to correlate genomic information with personality traits and mental health to understand the physiological effects in reproductive physiology.

In the last decade the controversy related to the effect of psycho-cognitive aspects and its main role in infertility has been solved, demonstrating that is a very important factor for physiology homeostasis and also health in reproduction. P5 medicine from a systems genomics approach is able to integrate all the patient information in a complex and multifactorial system that will allow us to understand in the next decade the detailed molecular relationship with reproductive physiology and the way to stratify patients in order to improve the infertility results and the patient experience in the infertility treatment.

Legal and Ethical Aspects of Female Reproduction

Heather E Ross, Ross & Zuckerman, LLP, Northbrook, IL, United States

Legal and Ethical Aspects of Female Reproductive Medicine

The practice of assisted reproductive technology ("ART") carries with it significant legal and ethical challenges, particularly in the area of third party reproduction. Because the physician's role will include treating both his/her patient (the intended parent(s)) and the "third party patient" (the gamete provider or surrogate), the physician should be aware of the potential for conflicting desires about medical treatment (i.e., an intended parent may desire a triplet pregnancy, while the surrogate may prefer to reduce). In addition, unlike other areas of medicine, the purpose of reproductive technology is to create a child, raising issues of disclosure and the rights of donor conceived offspring.

The laws in this area continue to evolve, and in many places remain unsettled or are based on strict compliance with the relevant statute or court practice. Not only do laws vary depending on the type of fertility treatment provided, but also by country, province, state and even counties or districts within a state. Prior to engaging in medical treatment the parties should consider how parentage to the child will be established, and how to ensure the gamete provider or surrogate is protected from financial and social responsibility.

Ethical Considerations

Medical Autonomy

One of the most interesting ethical dilemmas for physicians and lawyers involved in surrogacy arrangements is how to preserve the gestational surrogate's right to medical autonomy, while addressing the intended parent's desire to make medical decisions concerning the embryo transfer and health of the fetus. The physician should always confirm that the parties are in agreement with respect to the number of embryos transferred, termination and selective reduction, and all other health precautions/procedures each party agrees to follow before any party commences medication in furtherance of an embryo transfer to a gestational surrogate.

Physicians should be aware that federal laws protect the gestational surrogate's right to medical autonomy, including her right to terminate a pregnancy. The US Supreme Court frowned upon the notion of restricting a pregnant woman's activities in *Planned Parenthood of Southeastern Pennsylvania v. Casey*, holding that a husband's consent could not be required in order for his wife to obtain an abortion, and noting in dicta that, "if the husband's interest in the fetus' safety is a sufficient predicate for state regulation, the State could reasonably conclude that pregnant wives should notify their husbands before drinking alcohol or smoking." *Planned Parenthood v. Casey* (1992). Requiring medical treatment or procedures raises even more complex issues. Although parties to surrogacy agreements typically agree that the gestational surrogate will submit to medical procedures (i.e., ultrasound, amniocentesis, Cesarean section, etc.), the US Supreme Court has held that a person has a constitutionally protected right to refuse unwanted medical treatment or procedures (Ross, 2013–2014) (<http://www.dcba.org/mpage/vol261213art1>).

Notwithstanding a surrogate's right to medical autonomy, the US Supreme Court has held that parents have a constitutionally protected fundamental liberty interest in procreating and making decisions about how to raise their children. *Skinner v. Oklahoma*, 316 U.S. 535 (1942) (striking down legislation allowing for sterilization, Court found that "marriage and procreation are fundamental to the very existence and survival of the race") (*Skinner v. Oklahoma*, 1942). See also, (*Santosky v. Kramer*, 1982) (natural parents have a fundamental liberty interest in "the care, custody and management of their child"). See also, (*Stanley v. Illinois*, 1972) (the right to conceive and raise one's children is deemed essential and the "basic civil rights of man"), citing (*Skinner v. Oklahoma*, 1942).

If this interest is found to extend to decision making with respect to a fetus, it could potentially override a gestational surrogate's right to medical autonomy. Although the right of intended parent(s) to protect a fetus gestated by a third party has not yet been addressed by legislation or case law, the US Supreme Court has considered whether a state could have an interest in protecting fetal life. *Roe v. Wade* is the landmark decision granting a pregnant woman, along with her physician, the right to make decisions with respect to her pregnancy, including the right to terminate prior to fetal viability. However, *Roe* also recognized that a state could have a compelling interest in the potential life of a fetus ("if the State is interested in protecting fetal life after viability, it may go so far as to proscribe abortion during that period, except when it is necessary to preserve the life or health of the mother.") *Roe v. Wade*, 410 U.S. 113, 163–164 (1973). (*Roe v. Wade*, 1973)

Although jurisdictions differ with respect to whether a state's interest in protecting fetal life can override a women's right to medical autonomy, the majority of states will not force a woman to undergo medical treatment against her will. "When state courts have ordered competent pregnant women to undergo invasive medical procedures against their will, the decisions have almost invariably involved situations where the refusal of treatment was clearly and undeniably placing a viable fetus at severe risk". Wald, Deborah, esq. And Black, Katherine, J.D. Candidate, (2011) *Surrogacy and a Pregnant Woman's Constitutional Right to Medical and Procreative Choice – A Brief Survey*, www.waldlaw.net/assets/files/ABA%20surrogacy%20article.10.2011.pdf (Wald & Black Katherine, 2011)

Each Party's intent with respect to termination, selective reduction, and other medical issues affecting a surrogacy arrangement should be discussed prior to proceeding with medical treatment. Best practices also include independent legal representation and psychological consultations. Only through the process of thorough and open discussion can parties to surrogacy arrangements determine whether they are an appropriate match. A gestational surrogate who is opposed to amniocentesis or a Cesarean section should not be matched with intended parent(s) who want these procedures. The parties are much better off discovering any disagreements early on in the process rather than having a dispute arise during fertility treatment or pregnancy.

Physician Conflicts of Interest in Egg Donation Arrangements

In most practices, the physician treats both the intended parent(s) and the egg donor. Although intended parent(s) and egg donors have a unified purpose: obtaining viable embryos that will result in a successful pregnancy and birth, the means to achieve this outcome has inherent conflicts. The primary goal of one patient, the intended parent(s), is to create as many embryos as possible, so he/she has multiple chances at achieving pregnancy. The primary goal of the second patient, the egg donor, is to preserve her own health while also completing her donation. Many intended parent(s) can only afford one cycle of egg donation, and have experienced tremendous psychological and financial hardship and loss even before the use of donor eggs is recommended. To further complicate matters, typically the physician has known and treated the intended parent(s) long before the egg donor becomes a patient, further enforcing the feeling of the egg donor being the "third party" in the assisted reproductive arrangement.

In addition, the laws, or lack thereof, perpetuate this conflict. Pursuant to federal law, clinic's have a legal requirement to report fertility success rates in order to "help infertility patients make informed decisions about assisted reproductive technology." (See <https://www.fertilityauthority.com/articles/fertility-clinic-success-rates>.)

There is no corollary requirement to report any statistics demonstrating the medical affects or outcomes for egg donors (i.e., complications, amount of drugs used or number of eggs retrieved, etc.). In fact, the only federal regulations that do exist deal solely with truth in advertising (reporting statistics) and safety testing (i.e., to prevent donors from transmitting communicable diseases to recipients per FDA requirements). Although a few states have protective legislation (see, i.e., California, Arizona, and New York), and the American Society for Reproductive Medicine (ASRM), a self regulating association, has recommendations for informed consent, there are no federal laws that regulate informed consent, or what information must be provided to women who wish to donate their eggs (Cahn & Collins, 2014a).

Moreover, because reporting is required, and the higher the success rate the better the advertising for the clinic, the reporting mandate creates a financial incentive for clinics to achieve positive fertility outcomes and birth rates (Bass et al., 2014); (*Fertility Clinic Success Rate and Certification Act (1992)*). In short, all of these issues raise the question of whether the medical needs of the egg donor may be inadvertently overlooked in order to maximize the chances of a successful pregnancy.

Physicians should always focus on the best interests of both intended parent(s) and egg donors and balance the potential for conflicting desires. It may be helpful for reproductive physicians to look to physicians who work with living organ donors, as organ donation may be the most analogous situation to gamete donation (although without the ability to receive compensation). Federal laws governing organ donation require an independent donor advocate to make sure organ donors understand the risk they will be taking—with no medical benefit (*The Organ Procurement and Transplantation Network*, 2017).

Donor Gametes: Disclosure?

One of the most challenging issues for intended parents pursuing gamete donation is the decision of whether or not to disclose to the child that he/she was conceived with the help of a third party donor. Patients worry about how their child will react to this information, and whether the child will feel confused about her identity or whether knowing will jeopardize the child's ability to bond with her parents. "Simply put, parents want to know whether to tell their children of their genetic origins and if they do tell their children, how to talk to them about this complex subject" (Wilkins & Carole, n.d.) (Disclosure Issues Fact Sheet). Although there are no laws in the United States providing donor offspring the legal right to know the identity of her gamete provider, there has been a shift in practice in recent years moving away from strictly anonymous donor arrangements to more open exchanges of information between the intended parent(s) and the donor (though anonymous email exchanges or the donor Sibling Registry, see <https://www.donorsiblingregistry.com/>).

Mental health professionals agree that secrets in families are damaging and that children are better off knowing from a young age that they are not genetically related to one (or sometimes both) of their parents. Although donor conception has traditionally looked to adoption practices, including the dated belief that an adopted child did not need to know her origins, the adoption field has changed dramatically, and it is now well accepted that adopted children should have the right to know they are adopted and the identity of their birth parents (Cahn, 2014).

Several useful sources exist to obtain information regarding donor gametes and disclosure to donor conceived children (see <https://www.dcnetwork.org/>, www.resolve.org, www.path2parenthood.org, www.pved.org).

Legal Considerations

Lawyers practicing in this area spend much of their time drafting contracts between intended parent(s) and the third party provider, as well as drafting and reviewing consent forms between each patient and the fertility clinic. The ultimate purpose of these

documents is the creation of a child. They are not simple exchanges of property rights, and, therefore, the ART attorney must carefully explore and reflect their client's wishes, with detailed consideration of ethical issues inherent in these types of arrangements. Acknowledging the complexity of these arrangements and advising patients to consult with competent legal representation may be the most important advice a physician can provide to patients (and their third party patient) embarking on this family building journey ([Crocker & Debele, 2015](#)).

Sperm Donation

By the 1970s most states in the United States had passed laws addressing parentage rights with respect to children conceived from donor sperm. Although state laws differ with respect to how parentage is established, most state legislatures have found that sperm donation statutes will not apply to the birth of a child conceived by means of sexual intercourse. See ([Uniform Parentage Act, 2002](#)) ("This article does not apply to the birth of a child conceived by means of sexual intercourse"). The method by which the sperm is donated is often a determinative factor in establishing whether the sperm provider is a donor or parent. Many states require the sperm be donated through a licensed physician, while other states recognize a home artificial insemination (e.g., at the time of this article, in Texas, Kansas and Wisconsin the sperm must be provided through a licensed physician, while in Illinois and Florida a home insemination is permitted). Some state laws require the intended father's written consent, while others allow for implied consent. Some states require the parties to be married and some specifically terminate the rights of the donor. Failure to comply with the state statute can result in unintended consequences. For example, a Kansas sperm donor who gratuitously donated his sperm to a lesbian couple via a home insemination kit was later sued by the Kansas Department of Children and Families for child support—even though the parents of the child agreed that he was NOT a father and should not have any financial responsibility for the child. It took more than 4 years for the Kansas courts to relieve the sperm donor of child support obligations ([State of Kansas Ex. Rel. vs. W.M., 2016](#)). In short, complying with relevant statutes/case law is extremely important to protect the intent of the parties and parentage rights to the child.

Egg Donation

Although building families through egg donation is a much more recent medical advancement, by 2011 egg donation had already increased to 10% of all ART cycles ([Practice Committee of the American Society for Reproductive Medicine, 2014](#)). Laws pertaining to egg donation have been slow to follow, with only a handful of states specifically addressing egg donation ([Swain, 2014](#)).

Unlike sperm donation, where most states have passed laws and the main concern is correctly adhering to the law, in egg donation arrangements most states are silent on the issue of parentage, and although parentage laws typically consider the woman who gives birth to a child as proof that she is the child's mother, an intended mother has no legal guarantee that she will be considered the legal mother of the child. Because egg donation carries greater medical risk and is much more expensive and time consuming for the donor, many fertility clinics have put in place additional steps the participants must follow to attempt to make sure each party understands the medical, psychological and legal risks. For example, many clinics require independent legal counsel, a mental health consultation and detailed informed consent disclosures (although true informed consent may be somewhat lacking for many egg donors—see above). Many arrangements are governed by direct agreements between the egg donor and the intended parent(s). Entering into a direct agreement allows each party the opportunity to set forth his/her expectations of how the donor arrangement will work, both before any medications commence and during the egg retrieval process. Perhaps most important, it provides a legal framework for the parties to consider the potential for future contact if a medical reason arises, or should the child be curious about the donor's identity.

Unlike many European countries, compensating an egg donor is not prohibited in the United States. However such compensation must be premised on the gamete provider's time and inconvenience and should not be tied to the number or quality of gametes donated, or the ultimate outcome of the cycle. Paying for bodily parts is strictly prohibited (see [NOTA, 1984](#)). While a compensated sperm donor typically earns one lump sum payment for his "time and inconvenience" at the time of his deposit, an egg donor typically earns her compensation in phases as her "time and inconvenience" is spread out over several weeks. This allows for the possibility of an egg donor changing her mind or becoming disqualified part way through a cycle—resulting in uncertainty as to the amount of compensation she should receive. The direct agreement can set forth the agreed upon financial terms between the parties to avoid disagreement about payment terms should the arrangement terminate before the egg retrieval.

In sum, although there has been very little litigation in this area, intended parents and egg donors should meet with independent legal counsel to make sure they are protecting their rights and the rights of the donor conceived child.

Gestational Surrogacy

The ability to give birth to a child for someone who is unable to carry has been one of the most important medical advancements in third party reproduction. The earliest form of surrogacy, referred to as "traditional surrogacy" occurs when the surrogate is genetically related to the child, and is typically accomplished through intrauterine insemination. Today, as a result of in vitro fertilization, the more common and legally acceptable form of surrogacy is "gestational surrogacy", when the transferred embryo is not genetically related to the surrogate. Because the traditional surrogate is genetically related to the child she is carrying, issues surrounding traditional surrogacy are socially and psychologically complex, and most laws do not recognize the parental status of intended parent(s) working with a traditional surrogate (thus requiring an adoption proceeding). Gestational surrogacy has become an

acceptable practice to achieve parentage in the U.S., and several states have laws protecting the sanctity of these arrangements. However, a few states have laws strictly prohibiting gestational surrogacy, and a few impose criminal sanctions to all participants (including professionals). Failure to comply with the specific law can result in unintended and expensive consequences for both the intended parent(s) and the gestational surrogate and her spouse, as well as potential liability for the treating professionals.

Different states allow for different types of surrogacy arrangements. Some require that the intended parent(s) be genetically related to the child, while other states allow gestational surrogacy arrangements with a donated embryo (where neither intended parent is related to the child). While some states, including Illinois, make it easy to place both names of the intended parents on the original birth certificate at the time of birth with no court involvement (so long as strict statutory requirements are complied with), other states make the process more difficult, and require an adoption proceeding or adjudication of parentage. Making matters more complex, in some arrangements the parties reside in different states and it may be challenging to determine which state law should apply. Before commencing any medical treatment it is imperative the each participant consult with independent counsel to make sure the contemplated arrangement has legal protection and that the parties are complying with all legal requirements imposed by the relevant jurisdiction (see <http://www.creativefamilyconnections.com/us-surrogacy-law-map>, <http://familybuilding.resolve.org/fertility-scorecard/>).

EVALUATION

Overview: Evaluation and Male Reproductive Medicine

Samuel Ohlander, University of Illinois-Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Evolutionary theory correlates reproductive potential with self-worth. The male purpose is to pass their genes to the next generation. However simplified or antiquated this theory is, it is because of the belief that subfertility equates to inadequacy that physicians must approach the male fertility evaluation with sensitivity. It is a disease with physical, psychosocial, and economic implications, and most often must be evaluated in the context of a couple.

The normal couple carries pregnancy rates by intercourse of 20%–25% per month, 75% by 6 months, and 90% by 1 year (Spira, 1986). Approximately 15% of couples experience infertility, defined as the inability to conceive after 1 year of unprotected intercourse. In 40%–50% of these cases there is a male contribution, with approximately 20% solely male factor (Thonneau et al., 1991).

Often times, the male fertility evaluation is the first medical encounter that a man has had since being evaluated by his pediatrician. It is important to understand that a lack of diagnosis does not mean an absence of pathology. The chapters that follow will focus on the evaluation of the male. It is critical to consider the overall health of the patient, as subfertility has shown to be associated with other medical comorbidities, furthermore other comorbid conditions may offer explanation to reproductive dysfunction. The male fertility potential relies upon hormonal hemostasis, successful spermatogenesis, and intact erectile and ejaculatory function. Each component must be evaluated to establish an understanding of the patient's reproductive health.

Ultimately, the goal of evaluating the infertile male, and that which will be discussed in the following chapters, can be broken down into: 1. How to identify factors that may be modified to improve fertility potential. This requires an understanding of the male anatomy and physiology, particularly the hypothalamic-pituitary-testicular axis. 2. What diagnostic tools exist, and when they should be utilized in an evaluation. There is continuous evolution of diagnostic tools, many of which we as fertility experts are still trying to understand how best to interpret and utilize. 3. How to identify comorbidities and understand the role that existing pathology, and subsequent intervention, may play on male reproductive health. 4. How to approach care with financial consciousness. While health care economics is constantly evolving, and as such it is not a focus of this text, it is a significant factor in management of the infertile couple and must be a topic of consideration and discussion with our patients.

Clinical Evaluation of the Subfertile Male

Julie A Szymaniak and Martin Kathrins, Brigham and Women's Hospital, Boston, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Epidemiology

Infertility is defined clinically as a failure to achieve pregnancy after one year of having intercourse without birth control. When the female partner is older than 35 years, the infertile period is defined as 6 months or more. An estimated 48.5 million couples are affected by infertility worldwide, corresponding to a rate of 8–15% of childless couples.(WHO) The burden of infertility has remained relatively unchanged over the past two decades.(Mascarenhas et al., 2012) In the United States, about 15% of couples are unable to conceive after 1 year of unprotected sex.(Jarow, 2011) It has been often thought of as woman's problem, but in fact 20% of infertility cases are caused by male reproductive issues and an additional 30–40% of cases are due to both male and female issues.(Jarow, 2011) Thus, the evaluation and treatment of the male partner is a critical component of infertility.

History / Risk factors

The successful production and delivery of sperm requires a seamlessly functioning endocrine system via the hypothalamic-pituitary-gonadal axis as well as unobstructed passage through the male genitourinary tract. There are a plethora of conditions that can result in male infertility, and a thorough history taking is essential in the evaluation of a subfertile male. This includes inquiring into a patient's medical and surgical history, review of medications, exposure to occupational and environmental toxins, infections (both genitourinary and/or febrile), previously diagnosed pediatric conditions, and a detailed sexual history.

When taking a thorough history, special attention should be paid to risk factors that predispose the patient to erectile dysfunction, which is defined as the inability to maintain a sufficient penile erection for satisfactory sexual intercourse. These include increasing age and medical conditions such as diabetes mellitus, obesity, cardiovascular disease, hypertension, dyslipidemia, and benign prostatic hyperplasia. The patient's medications should also be reviewed, as certain antihypertensive agents and psychotherapeutic drugs have been associated with erectile dysfunction. Exposure to spermatotoxic agents should be assessed. For example, drugs that increase the ratio of estrogen to testosterone have been shown to impact sperm production. These include anti-androgens, corticosteroids, antiretroviral protease inhibitors, and exogenous estrogen. Exposure to chemotherapy and radiation, as well as prior genitourinary tract infections, should also be queried. Childhood genitourinary diseases, such as testicular torsion and cryptorchidism (or undescended testes) may also impact reproductive outcomes later in life. Lastly, assessing a couple's sexual activity to ensure optimal timing of intercourse, avoidance of spermatotoxic lubricants, and ejaculatory function is important.

Physical Exam

A general physical exam may be helpful in elucidating the cause of a male's infertility. The lack of secondary sexual characteristics, such as pubic hair, or the presence of gynecomastia (breast enlargement) can suggest inadequate androgenization. The scrotum should be examined for the presence of masses or swelling. The testes should be measured for size, as a testicle that is < 4.6 cm in length or 20 mL in volume is associated with spermatogenic dysfunction.(Brannigan and Laborde, 2016) The vas deferens must be evaluated on both sides, as absence of the vas deferens on one side suggests a possible embryologic malformation, indicating possible renal agenesis. Absence of the vas deferens on both sides, or congenital bilateral absence of the vas deferens (CBAVD), is associated with cystic fibrosis disease or carrier status and warrants a genetic workup for the male and female partners. The penis should be inspected and the location of the urethral meatus should be noted. The groin should be assessed for the presence or absence of an inguinal hernia. A digital rectal examination may also be performed to evaluate the prostate and seminal vesicles.

Laboratory Evaluation

Endocrine assessment includes evaluating levels of total testosterone, estradiol, and LH and FSH. Spermatogenesis, or the development of sperm cells within the male reproductive organs (testes), relies on central and testicular hormonal feedback mechanisms. Gonadotropin-releasing hormone (GnRH) is released by the hypothalamus and causes the anterior pituitary to secrete gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These act locally within the testes, with LH acting on Leydig cells to produce testosterone and FSH stimulating Sertoli cells to produce sperm cell precursors. Germ cells interact intimately with Sertoli cells and modulate the release of FSH. Thus, FSH can be used as an indirect measure of germ cell volume. Combined with testicular size, FSH can help differentiate between a male with azoospermia (complete absence of sperm in ejaculate) due to obstruction versus spermatogenic impairment. Men with obstructive azoospermia have low FSH levels with larger testes while men with spermatogenic dysfunction have high FSH levels with smaller testes.

When analyzing semen samples, specifically sperm concentration, there is no absolute cut off to discern the infertile from the fertile male, aside from complete azoospermia. However, typically sperm counts in the 5th percentile or lower likely represent infertility, whereas men with sperm counts in the 50th percentile or higher will likely be able to conceive. Such a semen analysis should be performed twice to account for significant variability among bulk semen parameters within a given male patient. Semen volume can also be of clinical importance. Semen hypovolemia is defined as a volume of <1.0 mL. In such a setting, post-orgasmic urinalysis should be obtained, which can help differentiate between ejaculatory ductal obstruction and retrograde ejaculation.

Medical Management

Hormonal disorders account for a small number of cases of male infertility (<3%), and can be divided into disorders of hormonal deficiency and hormonal excess.

Hormonal Deficiency

Gonadotropin deficiency causes hypogonadotropic hypogonadism, a condition in which low levels of LH and FSH lead to testosterone deficiency. The condition may be congenital, such as Kallmann's syndrome, which is associated with dysfunction of the olfactory system, or acquired, such as pituitary tumors or trauma. This condition can be treated with replacement of gonadotropins, by using agents such as human chorionic gonadotropin (hCG), human menopausal gonadotropin (hMG), or recombinant follicle-stimulating hormone (r-FSH). hCG is an LH agonist that stimulates intratesticular testosterone production by Leydig cells. hMG and r-FSH stimulate spermatogenesis by supporting Sertoli cells. Anti-estrogen agents, such as clomiphene citrate, are also used. These work by binding to estrogen receptors in the hypothalamus and anterior pituitary gland, thereby blocking estrogen's negative feedback inhibition of gonadotropin release. The goal of treatment with the above-mentioned agents is to increase testosterone levels to normal and to optimize spermatogenesis.

Alternatively, hypergonadotropic hypogonadism is caused by primary testicular dysfunction. In this condition, gonadotropins are inappropriately elevated due to the lack of negative feedback from testosterone, estradiol, and inhibin from the testes. Again, spermatogenesis is impaired due to low levels of testosterone. The condition can be congenital, such as Klinefelter Syndrome diagnosed when a supranumerary X chromosome is noted on a karyotype, or acquired, such as following chemotherapy, radiation therapy, or genital mumps infection. Medical treatment of hypergonadotropic hypogonadism is not well standardized, but may include aromatase inhibitors, gonadotropins, and anti-estrogen agents. Aromatase inhibitors work by inhibiting the enzyme aromatase, which converts testosterone into estradiol. By inhibiting the conversion of testosterone, higher levels of it should be available to stimulate spermatogenesis. Gonadotropin agents such as hCG, hMG, and r-FSH can be used in combination with aromatase inhibitors and anti-estrogen agents rather than as single agents. Similarly, anti-estrogen agents are not used alone in treatment of hypergonadotropic hypogonadism. Both classes of these drugs aim to augment the already elevated levels of gonadotropins.

Hormonal Excess

Hormonal excess is typically seen in patients receiving exogenous androgens, such as anabolic steroids. The use of these agents causes suppression of intratesticular testosterone production and thereby decreases or stops spermatogenesis. Treatment involves stopping exogenous steroids, and some men may require additional hormonal therapy. After cessation of exogenous androgens, spermatogenesis may resume within 3 months, although it may take up to 3 years.

High levels of prolactin can lead to disruption of the hypothalamic-pituitary-gonadal axis, as prolactin excess inhibits the hypothalamic secretion of GnRH. Causes of prolactin excess include prolactinomas (tumors of the pituitary), hypothyroidism, liver disease, stress, and certain medications. Treatment involves addressing the underlying cause as well as the use of dopamine agonists, such as bromocriptine. These agents work by blocking prolactin secretion by the pituitary.

Erectile Dysfunction

Impaired sexual function can impact fertility by hindering a couple's ability to successfully engage in intercourse. About one-fifth of men presenting for treatment of infertility have erectile dysfunction. (Shindel et al., 2008) As mentioned above, several risk factors and comorbidities are associated with erectile dysfunction. It can be caused by organic pathologies, such as decreased blood flow or nerve impairment, or by psychological issues. Treatment includes addressing underlying medical issues, patient counseling and medical therapy with oral or local agents. If a patient is not satisfied with his erectile function with oral or local agents, then referral to a male sexual health specialist is indicated.

Ejaculatory Dysfunction

In order for a couple to successfully conceive through sexual intercourse, antegrade ejaculation (forward flow) of semen must occur. Antegrade ejaculation requires the sympathetically-induced emission of sperm and bladder neck closure with somatic nerve-controlled pelvic floor muscle contractures. When diagnosing and treating ejaculatory dysfunction, it is helpful to divide the condition into retrograde ejaculation and failure of seminal emission.

Retrograde ejaculation is the backwards flow of semen into the bladder during ejaculation. It should be suspected in patients with low semen volume or absence of ejaculation during orgasm. Conditions associated with retrograde ejaculation include congenital abnormalities of the bladder neck, neurologic injury, retroperitoneal lymph node dissection, and diabetes mellitus. (Wein et al., 2012) Evaluation of retrograde ejaculation includes analyzing post-orgasmic urinalysis. In patients with sperm noted in that urinalysis, a diagnosis of retrograde ejaculation can be made. Treatment includes alpha-adrenergic agonists, such as pseudoephedrine, and tricyclic antidepressant agents, such as imipramine, which act to close the bladder neck during climax by stimulating sympathetic nerves. Failure of emission is suspected in patients who do not have sperm on post-orgasmic urinalysis. Typically these patients fail with medical therapy, and often require sperm extraction procedures. Such patients should be evaluated with a transrectal ultrasound to evaluate the seminal vesicle and ejaculatory duct anatomy.

Infection and Inflammation

Infection and inflammation of the male genitourinary tract can have a detrimental effect on sperm function and viability. Patients may present with infection, inflammation, or both. Infectious organisms include *Escherichia coli*, mycoplasma, ureaplasma, and sexually transmitted bacteria, such as chlamydia trachomatis and Neisseria gonorrhea. Clean-catch sperm cultures should be collected and treated with antibiotics or antivirals if found to be positive, however such cultures are often contaminated. Results should be interpreted with caution. Additionally, inflammation may be present without an infection. Leukocytospermia, or white blood cell counts of > 1 million/mL, may have an adverse effect on sperm function, although this is controversial. The suggested mechanism is through reactive oxygen species, which are released by white blood cells and cause cellular damage. Proposed treatments include anti-inflammatory medications, antioxidants, or anti-histamines to reduce oxidative-stress induced sperm damage.

Surgical Management

Surgical intervention can be used to treat certain conditions resulting in male infertility, and can be divided into procedures that optimize spermatogenesis, improve sperm delivery, and retrieve sperm. (Brannigan and Hotaling, 2016).

Surgical procedures that optimize spermatogenesis involve varicocele correction. Varicoceles are abnormal dilations in the pampiniform plexus of veins within the spermatic cord. Although they are common and occur in about 15% of males, the majority of varicoceles do not cause infertility. Only palpable varicoceles have been shown to be associated with spermatogenic decline and are surgically treated in the setting of abnormal semen parameters.

Procedures that optimize sperm delivery do so by relieving ejaculatory duct obstruction (EDO) or by re-establishing ductal patency after a prior vasectomy. Semen analysis can help determine the diagnosis of EDO. With EDO, semen volume is low given that most of the ejaculate volume is seminal vesicle fluid, which will be unable to pass into the urethra. Furthermore, without seminal vesicle secretions, the ejaculate is often acidic ($\text{pH} < 7$) and lacks fructose.

Sperm retrieval procedures range from needle aspiration of sperm through the skin to open surgical exploration of the testicle to find viable sperm. If a patient is azoospermic due to obstruction, then successful retrieval rates of up to 100% can be expected.

Conclusion

Male factor infertility commonly contributes to a couple's inability to conceive. Therefore, the male partner should always undergo a fertility evaluation with referral to a male reproductive specialist in the setting of any abnormalities.

Male Reproductive Endocrinopathy: Evaluation

Tolulope Bakare and Neha Malhotra, University of Illinois at Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

In 20%–40% of infertility cases, male factor is either solely responsible, or a contributory factor, respectively (Thonneau et al., 1991). While one, office-based analysis, showed that only 1.5% of male infertility cases are finally diagnosed with endocrinologic abnormalities, a working understanding of the possible endocrinopathies is essential to evaluation of the infertile male (Sigman et al., 2009). Endocrine disorders leading to infertility are often correctable and may need further treatment outside the realm of fertility.

History and Physical Exam

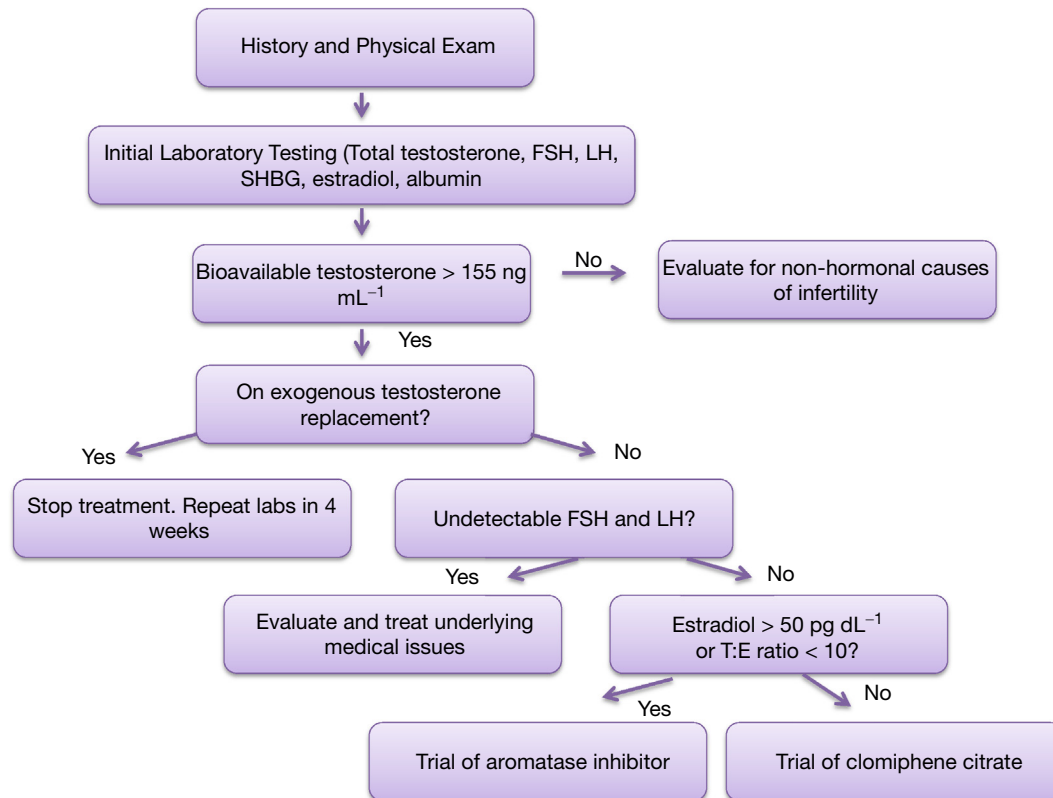

The history and physical exam is integral to the evaluation of the infertile male. In addition to a standard history, a reproductive history should include duration of infertility, prior fertility, developmental history (including childhood viral illness), sexual history (including sexual transmitted infections), genital or pelvic trauma, radiation history, coital frequency, use of lubricant, gonadotoxin exposure as well as familial fertility history (Jarow et al., 2002). Prior fertility rules out a number of congenital endocrinologic issues. A thorough medication history may reveal medications that may alter or disrupt normal endocrine function. Endocrine mimicking and disrupting chemicals can alter the balance of testosterone to estrogen and interfere with the hypothalamic-pituitary-gonadal axis. These include prescription medications such as antiandrogens (bicalutamide, flutamide, finasteride, and dutasteride), spiro-nolactone, protease inhibitors (saquinavir, indinavir, nelfinavir, ritonavir), nucleoside reverse transcriptase inhibitors (stavudine, zidovudine, lamivudine), exogenous testosterone, estrogen or steroids as well as histamine₂-blockers (cimetidine) (Bowman et al., 2012). Opioids suppress luteinizing hormone (LH) release and also disrupt the hypothalamic-pituitary-gonadal axis (Subiran et al., 2011). As opioids become increasingly commonly prescribed and abused, it is critical to ask about their use during the medical history. Other medications such as antifungals (ketoconazole), calcium-channel blockers, first general antipsychotics and chemotherapy may also affect the hypothalamus-pituitary-gonadal axis. Nonprescription drugs, such as marijuana and alcohol can also cause a decrease in androgens and worsening of bulk semen parameters. Surgical history should be noted for cryptorchidism, hypospadias repair, vasectomy, as well as pituitary resection. Physical exam should note the degree of virilization and secondary sex characteristics such as body habitus; hair pattern and gynecomastia. Shape, consistency, and size (in volume or testicular long axis) of testis should be recorded as well as cryptorchidism, varicocele, and whether or not the vasa are palpable bilaterally as well as the epididymal consistency. The testes volume is measured with an orchidometer or calipers. Testes size < 15 cm³ by Prader orchidometer are associated with abnormally low sperm concentration, and may be associated with a low testosterone production (Sigman et al., 2009). The penis should also be examined for meatal position. While rare, micropenis is often associated with endocrinologic abnormalities and should also be noted. Digital rectal exam should be performed to rule out masses. Besides discerning the etiology of infertility, a thorough medical evaluation is essential as 1.1%–1.3% of men presenting to an infertility clinic will be diagnosed with previously unknown, serious medical illness (Kolettis and Sabanegh, 2001; Honig et al., 1994). These men must further be counseled that their infertility in itself may be associated with future metabolic illness such as diabetes (hazard ratio [HR] 1.3, 95% confidence interval [CI] 1.10–1.54) and ischemic heart disease (HR 1.48, 95% CI 1.19–1.84) (Eisenberg et al., 2016).

Initial Laboratory Testing

After a complete history and physical exam, initial laboratory testing should be undertaken. Often, men will be referred with a semen analysis, but if not, one should be obtained. Men are typically instructed to wait 1–2 days after ejaculation to obtain an analysis; however, in a recent single-center, retrospective review of over 15,000 men it was found that longer abstinence time was not associated with improved sperm concentration, total sperm count or total motile count for men with oligospermia (Keihani et al., 2017; Levitas et al., 2005). While some authors recommend endocrinologic evaluation only if there is low sperm concentration, impaired sexual function or signs and symptomatic of an endocrinopathy, we recommend a screening androgen profile for all patients as a certain percentage of men with normal sperm density will have difficulty conceiving and an identifiable cause on endocrine evaluation (Jarow et al., 2002). Male androgen profile includes follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol, total testosterone, sex-hormone binding globulin (SHBG), and albumin (the latter two to calculate the bioavailable testosterone). Androgen profile should be obtained in the morning, as testosterone is released in pulsatile fashion and peaks in the morning and a single random measurement of testosterone serum level may not accurately reflect the mean serum concentration. This initial evaluation can give a glimpse into possible underlying etiologies of infertility (see Table 1). Some authors advocate for routinely checking prolactin levels at the initial evaluation. If thyroid disorder is known or suspected, thyroid-stimulating hormone (TSH) should also be ordered. Similarly, if diabetes mellitus is known or suspected, consideration should be given to checking a fasting glucose or hemoglobin A1c level.

Table 1 Endocrinologic etiologies of male factor infertility

<i>Etiology</i>	<i>Testosterone</i>	<i>FSH</i>	<i>LH</i>
Normal spermatogenesis	Normal	Normal	Normal
Abnormal spermatogenesis	Normal	↑/Normal	Normal
Hypogonadotropic hypogonadism	↓	↓	↓
Hypergonadotropic hypogonadism	↓/Normal	↑	↑

**Fig. 1** Initial evaluation of the infertile male: hormonal dysfunction. Adapted from Kathrins, M. & Niederberger, C. (2016). Diagnosis and treatment of infertility-related male hormonal dysfunction *Nature Reviews Urology* **13**(6), 309–323.

If there are abnormalities of these initial screening tests, further investigation must be undertaken (see Fig. 1). If the bioavailable testosterone (as calculated from the total testosterone, SHBG and albumin is $> 155 \text{ ng mL}^{-1}$, nonendocrinopathy causes of infertility should be considered. The ratio of testosterone to estradiol (T:E) can be used to consider different treatment options such as aromatase inhibitors (T:E < 10) or nonsteroidal selective estrogen receptor modulators (T:E > 10). Specific endocrinopathies are discussed later on in this section.

Hypothalamic-Pituitary-Gonadal Axis

In order to understand the etiologies and implications of these laboratory abnormalities, the hypothalamic-pituitary-gonadal axis must be understood (see Fig. 2). Gonadotropin releasing hormone (GnRH) is synthesized in the preoptic nucleus in the anterior hypothalamus and then released in the hypophyseal portal bloodstream where it is carried to the pituitary gland. By activation of the GnRH receptor a signal cascade is initiated, which stimulated the synthesis and secretion of FSH and LH from the anterior pituitary. FSH and LH are also known as gonatropins and share the same alpha subunit; the beta subunit makes them distinct from one and other and interacts with their respective membrane bound receptors. Gonadotropin release is dependent on pulsatile activation of the GnRH receptor. Continuous secretion of GnRH essentially turns off FSH and LH secretion. FSH and LH then stimulate testicular function. FSH stimulates spermatogenesis in the Sertoli cells, as well as synthesis of Inhibin B. Whereas LH stimulates the Leydig Cells to increase expression of 17 β -hydroxysteroid dehydrogenase, which regulates the conversion of androstenedione to testosterone. Testosterone exists in both the free form, and bound to SHBG as well as albumin. Free and albumin bound testosterone

Fig. 2 Hypothalamic-pituitary-gonadal axis. GnRH, gonadotropin release hormone; GnIH, gonadotropin inhibiting hormone FSH, follicular stimulating hormone; LH, luteinizing hormone. Adapted from Kathrins, M. & Niederberger, C. (2016). Diagnosis and treatment of infertility-related male hormonal dysfunction. *Nature Reviews Urology* **13**(6), 309–323.

is considered to be active. Leydig cells are a site of steroidogenesis and also synthesis dihydrotestosterone as well as estradiol. Testosterone is also converted into dihydrotestosterone in the prostate, as well as to a lesser degree in the epididymis, through the action of 5α -reductase. Testosterone is peripherally converted to estradiol through the action of aromatase, principally in the adipose tissues. Excess gonadotropin or hormone causes feedback, which shuts off the system. For example, exogenous testosterone use results in an overabundance of testosterone, which is then converted into estradiol by aromatase. Estradiol inhibits LH secretion by the anterior pituitary and GnRH synthesis by the hypothalamus. Similarly, Inhibin B inhibits secretion of FSH by the anterior pituitary. Aberrations of this hypothalamic-pituitary-gonadal axis are discussed in detail further in this section.

Endocrinopathies of Male Infertility

Hypogonadism

Primary

Hypergonadotropic hypogonadism is characterized by low (hypogonadic) or normal testosterone in the setting of elevated FSH and LH (hypergonadotropic). This is also known as primary testicular failure or primary hypogonadism. This may be associated with gonadotoxic exposure such as mumps orchitis, radiation, chemotherapy, trauma or torsion; though this will usually be revealed early in the work-up of infertility.

Klinefelter syndrome one of the most common causes of primary testicular failure. Men with Klinefelter typically have a 47, XXY karyotype with mosaicism present in approximately 10% of these patients. Klinefelter should be suspected in especially tall men with gynecomastia, small, firm testis but many patients do not have this phenotype. Diagnosis is confirmed by aneuploidy on karyotype. Mosaicism is associated with less severe phenotypes and these men may be fertile. Successful pregnancy has been achieved using extracted sperm and then intracytoplasmic sperm injection (ICSI) even in nonmosaic Klinefelter patients (Greco et al., 2013).

Secondary

Hypogonadotropic hypogonadism is characterized by low testosterone (hypogonadic) as well as low FSH and LH (hypogonadotropic). This is known as secondary testicular failure or secondary hypogonadism and warrants further evaluation. If prolactin was not previously checked, serum prolactin levels should be ordered in the case of low testosterone with low gonadotropins. Prolactin can be a very volatile molecule and a single elevated result should prompt a repeat. If prolactin levels are truly high and symptoms are present, MRI should be ordered to evaluate for a pituitary tumor. Symptoms of a clinically significant pituitary adenoma usually include visual field changes (from compression of the optic chiasm), headache and erectile dysfunction. Typically, treatment involves pituitary resection; however, radiation and medical therapy with cabergoline and bromocriptine are also options (Brugh and Lipshultz, 2004). Pituitary tumors are typically not metabolically active and hypogonadotropic effect is caused by mass effect

on the anterior pituitary, change in blood supply and negative feedback on the hypothalamus. While pituitary adenomas may cause secondary hypogonadotropic hypogonadism, surgery for these adenomas can cause the same. Pituitary resection and trauma are acquired forms of secondary testicular failure. Certain medications, such as selective serotonin reuptake inhibitors, commonly prescribed for depression, may cause hyperprolactinemia as well. Again, highlighting the need for a thorough history in cases of male infertility.

Kallman syndrome is a genetic form of hypogonadotropic hypogonadism associated with a mutation of the KAL gene on Xp (Layman et al., 1992). This gene is associated with normal migration of hypothalamic neurons to the midline, and as such, patients tend to have anosmia and may also have cleft lip or cleft palate. While genetic testing is available, there are mutations associated with Kallman syndrome that are not readily identified and as such, a negative genetic test cannot rule out Kallman syndrome. Idiopathic hypogonadotropic hypogonadism is presumed to have an unrecognized genetic mutation.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is caused by enzyme mutations in the steroid synthesis pathway such that there is decreased production of glucocorticoid. Severity depends on which particular enzyme is deficient or mutated. As there is decreased glucocorticoid present and thus decreased feedback on the pituitary, there is an increase in adrenocorticotrophic hormone (ACTH) and overstimulation of the adrenal gland. This overstimulation causes hypersecretion of adrenal androgens and leads to negative feedback on the pituitary and decreased production of LH (Bonaccorsi et al., 1987). As a result, LH is typically found to be low in CAH patients; FSH can be high due to adrenal rest tissue present in the testis (King et al., 2016). Adrenal rests may be suggestive of inadequate replacement of glucocorticoids. In females, in infancy, CAH can be life threatening but in males it may not present until much later as either precocious puberty, or even later as infertility. If CAH is suspected, diagnosis is confirmed by plasma testing for hydroxyprogesterone and urinary excretion of 17-ketosteroid.

Exogenous Steroid Use

Exogenous steroid use may also be associated with secondary testicular failure. Exogenous testosterone (and the converted by-product estradiol) feedback and shut off production of GnRH and LH. Without pulsatile GnRH there can be no FSH synthesis and so spermatogenesis ceases. Similarly, as there is no LH, intratesticular testosterone synthesis stops. These patients may have testicular atrophy on exam. Discontinuation of exogenous steroids should allow for wear off in approximately 4 weeks, but cases have been reported of unmasking subfertility and having persistent hypogonadotropic hypogonadism (Jarow and Lipshultz, 1990). Recovery of spermatogenesis has been demonstrated; with 67% of men recovering at 6 months, 90% within 12 months, 96% within 16 months, and 100% within 24 months (Liu et al., 2006).

Glossary

Seminal vesicle The seminal vesicles are a pair of tube-like glands. They are found behind the bladder of males. They make about 70% of the content of semen (also called seminal fluid).

Sympathomimetics Sympathomimetic drugs mimic the effects of sympathetic activation and cause smooth muscle contraction and vasoconstriction.

Abbreviations

DM Diabetes mellitus

EEJ Electroejaculation

IUI Intrauterine insemination

SVs Seminal vesicles

T Thoracic

The Anatomy and Physiology of Ejaculation

Various anatomical structures, all of which are controlled by the central and peripheral nervous systems, participate in the formation of semen. The testicles only produce 1%–2% of the total volume of semen while the seminal vesicles (SVs) produce up to two-thirds of the volume of the ejaculate. In addition, the SVs produce two essential components of the ejaculate, namely fructose and seminogelins, which facilitate the coagulation of the semen (Ohl et al., 2008). The prostate produces a third of the volume of the ejaculate as well as prostate specific antigen (PSA). PSA is a proteolytic enzyme that acts on the seminogelins to produce seminal fluid. To produce the total volume of the ejaculate, the bulbourethral or Cowper glands are also involved. These glands produce a clear mucosal secretion which is liberated during sexual stimulation. This secretion neutralizes the traces of acid from the urine which could otherwise damage the sperm (Chughtai et al., 2005). Once the seminal liquid is formed, it is deposited in the posterior urethra through the ejaculatory ducts. The internal sphincter or bladder neck, which is located proximal to the ejaculatory ducts, contracts during the emission of semen to avoid retrograde ejaculation toward the bladder. The external sphincter, located distal to the ducts, must open during ejaculation to allow the semen to exit the body. This entire process is coordinated by the central nervous system. The brain receives erotic stimuli and the signals originating in the upper central nervous system descend to the sympathetic thoracolumbar nerve centers (T10–L2), which provoke the contraction not only of the SVs and vas deferens, but also of the internal sphincter/bladder neck. Along with this latter action to stop any retrograde ejaculation, a series of involuntary rhythmic contractions of the periurethral muscles occurs, provoking a pulsating, projectile ejaculation, causing the propulsion of liquid semen from the penis. This mechanism goes into effect upon stimulation of the dorsal nerves of the penis, which reach the spinal medulla at the S2–4 level. The efferent vessels originated at this level travel along the pudendal nerve to the periurethral muscles, causing them to contract. The integrity of this arc reflex can be assessed through an exploration of the bulbocavernosus reflex. Sperm is not stored in the SVs, where the biochemical conditions could damage them and lower their motility. Rather, spermatozoa are stored in the epididymal tail. Only in cases of prolonged abstinence, partial obstruction of the ejaculatory ducts, or spinal cord injuries are sperm stored in the SVs (Ohl et al., 1999). In response to sexual stimulation, they rapidly move through the vas deferens during the emission of semen. The sperm which remain in the vas deferens are not released and they return to the epididymal tail.

Pathologies Associated With Ejaculatory Dysfunction

Iatrogenic

Retroperitoneal surgery

This type of surgery, which includes retroperitoneal lymphadenectomy, comprises one of the potential treatments for testicular tumors, both in stage I and stage II as well as in cases of residual retroperitoneal masses after chemotherapy (Basiri et al., 2013).

This type of tumor occurs primarily in young men and, as a result, it is a frequent reason for specialist consults for secondary ejaculation dysfunction due to this type of surgery. Other surgical procedures of this sort must also be taken into account, including aortic surgery. During resection, the nerves from both the sympathetic chain ganglia and the hypogastric plexus are eliminated, which in turn eliminates the efferent stimuli for the emission of semen and the closure of the internal sphincter/bladder neck. Recent technical modifications to this type of lymphadenectomy try to preserve these nerves ([Donohue et al., 1990](#)), with the most important zones being the preaortic hypogastric plexus below the lower mesenteric artery and the postganglionic sympathetic nerves at the T10-L2 level. One study comparing this innovative method to the classic surgical technique found that 99% of patients who underwent the former maintained anterograde ejaculation compared to 89% who underwent the classic surgery that did not preserve the nerves ([Beck et al., 2010](#)). Nevertheless, [Basiri et al. \(2013\)](#) analyzed the outcomes of modified lymphadenectomy with nerve preservation and found that only 61% of patients had anterograde ejaculation after treatment. With this type of surgery, the sacral afferents that provide sensitivity to the penis and glans remain intact, as do the sacral efferents, which produce the periurethral contractions necessary for the expulsion of semen. In this case, patients maintain the ability to achieve orgasm, although there may be no emission of semen due to the absence of contractions in the vas deferens, SVs, and ejaculatory ducts, which keeps the seminal liquid from reaching the prostatic urethra. This is called a “dry” orgasm.

Pelvic surgery

Ejaculatory alterations are a common problem after colorectal surgery. In one retrospective study, 47% of 207 patients who had undergone surgical treatment for a rectal tumor later presented with anejaculation ([Nishizawa et al., 2011](#)). This is because both the sympathetic and the parasympathetic nerves are located close to the mesorectal fascia. The total mesorectal cleavage technique preserves this entire autonomous plexus, leading to fewer cases of ejaculatory alteration. Alternatively, the use of laparoscopic techniques likewise decreases the likelihood of ejaculatory dysfunction ([Nagpal and Bennett, 2013](#)).

Prostate surgery

The most common causes of retrograde ejaculation due to anatomical changes are simple prostatectomy and transurethral prostatic procedures such as transurethral resection, photovaporization, and neck incisions. All these procedures are indicated for the treatment of secondary obstructive symptoms due to the enlargement of the prostate and they all produce “involuntary” damage to the fibers of the external sphincter and the bladder neck, which become incompetent, thus contributing to retrograde ejaculation. In the past, Y–V (Young–Dees) bladder neck plasty was widely used for cases of voiding dysfunctions and incontinence in pediatric patients. This technique is no longer used, but patients who underwent this intervention in the past may need fertility treatments.

Pharmacology

The alpha-blocker drugs used to treat lower urinary tract infections caused by an enlarged prostate may produce retrograde ejaculation as an adverse side effect. Another group of drugs that produce ejaculatory alterations are high blood pressure medications, antipsychotic drugs, and antidepressants.

Neurological Diseases

The main problem for patients with multiple sclerosis (MS) is erectile dysfunction. Nevertheless, ejaculatory problems are also frequent and include premature ejaculation (60%), retrograde ejaculation, anejaculation (33%), and delayed ejaculation ([Previnaire et al., 2014](#)). Because the sympathetic center for ejaculation is located in the thoracolumbar segments of the spinal cord, the effects that MS has on this part of the body are the cause of these dysfunctions ([Zivadinov et al., 1999](#)).

Diabetes Mellitus

The autonomic neuropathy (both sympathetic and parasympathetic) as well as the micro cardiovascular disease common in patients with long-term diabetes mellitus (DM) ([Phillips et al., 2014](#)) causes various ejaculatory alterations, such as anejaculation and retrograde ejaculation. In these patients, the former is caused by a lack of peristalsis in the vas deferens and SVs, which hinders the deposition of semen in the posterior urethra. However, retrograde ejaculation is the most frequent ejaculatory dysfunction in this cohort ([Gaubay et al., 2013](#)). The closure of the internal sphincter/bladder neck is controlled by the sympathetic nerve fibers. The neuropathy that DM produces in these fibers reduces the pressure of the closure at the moment that semen is released, thus leading to retrograde ejaculation. One study carried out on a cohort of young men with DM (mean age: 36 years) found that 6% suffered anejaculation or retrograde ejaculation ([Dinulovic and Radonjic, 1990](#)). In another study, out of 500 men who consulted a physician for infertility, only 5 (1.1%) had type I diabetes ([Sexton and Jarow, 1997](#)). To date, the real incidence of retrograde ejaculation or anejaculation among men with DM remains unclear ([Gaubay et al., 2013](#)).

Spinal Cord Injuries

The type of ejaculatory dysfunction in patients with spinal cord injuries depends on both the level and the degree of injury. For example, in cases of *high spinal cord injuries* (complete cervical or thoracic injury), the communication between the nerve centers of the central nervous system and the spinal cord center for ejaculation, known as the sympathetic thoracolumbar center, is blocked,

with the arc reflex remaining intact at the sacral level. In these cases, the patient may experience reflex erections. If ejaculation occurs, it will also be a reflex reaction. In the case of *low spinal cord injuries* below the sympathetic centers, when ejaculation occurs, it tends to be weak and drooling.

Idiopathic

In some patients it is impossible to determine the exact physiological cause of ejaculatory dysfunction, fundamentally cases of anejaculation. Although an underlying neurological or physical problem may exist without having been diagnosed, most of these cases have a psychological origin (Ohl et al., 2008). In these cases, a patient's medical history may be revealing. Many reach orgasm and have ejaculations when masturbating, but not during sexual intercourse (Perelman and Rowland, 2006). These patients are often unable to reach orgasm during sexual relations because of frequent masturbation or the use of idiosyncratic masturbation techniques. Modifying the stimulation techniques used and reducing the frequency with they masturbate often reverses the problem (Perelman and Rowland, 2006). If, despite sex therapy, problems with anejaculation persist, electroejaculation (EEJ) or vibrostimulation techniques may be used (Perelman and Rowland, 2006). Alternatively, sperm may be collected surgically to be used later in assisted reproduction techniques.

Evaluation of Ejaculatory Dysfunctions

For these patients, obtaining an accurate medical history is essential, especially because patients often confuse the symptoms of erectile dysfunction with ejaculatory dysfunction. An accurate medical or surgical history can help identify risk factors, such as retroperitoneal surgery or a history of DM. Likewise, any medications taken by the patient should be analyzed to assess whether they could be altering ejaculation. During the physical examination, testicle size should be assessed since it can indicate problems with spermatogenesis (e.g., a longitudinal axis smaller than 4.5 cm) (Schoor et al., 2002), or, if there are one or two vas deferens, it could be a possible case of obstructive azoospermia. In addition, the position of the urethral meatus should be checked to ensure that any infertility is not due to the anomalous outflow of semen due to hypospadias. As for complementary testing, follicle stimulating hormone and testosterone levels should be examined to help determine whether there is a problem with spermatogenesis. Glycemic levels should also be tested to identify any unidentified underlying pathologies, such as DM. In cases where the semen is not expelled or where the sperm volume in the spermogram is found to be low (< 1.5 mL) despite maintaining the ability to achieve orgasm, the post-orgasm urine should be analyzed to rule out retrograde ejaculation, which is taken to be the presence of 10–15 sperm per high-growth field after centrifugation of the urine (Sabanegh and Agarwal, 2012). If the post-orgasm urine does not contain sperm, a transrectal sonogram should be performed to rule out any obstruction of the ejaculatory ducts.

Treatment of Ejaculatory Dysfunctions

Drugs

If the patient is taking alpha-blockers or antidepressants, these should be discontinued and tests should be carried out to check whether the ejaculatory dysfunction is solved. Administration of sympathomimetics may be useful in certain circumstances as they transform retrograde ejaculation into anterograde ejaculation through contraction of the internal sphincter/bladder neck. In the absence of any spinal cord injury or anatomical changes in the urethra, ejaculation can be induced by various drugs (Table 1; Jungwirth et al., 2012). In addition, and as an alternative, the patient should be told to try to ejaculate with a full bladder so that the pressure is increased at the level of the internal sphincter/bladder neck, thus favoring anterograde ejaculation (Crich and Jequier, 1978). In cases where anterograde ejaculation is achieved, drugs can be taken in cycles during the week prior to ovulation and discontinued during the rest of the partner's cycle or taken several hours before intercourse. Collecting post-orgasm urine to use in subsequent assisted reproduction techniques should be recommended when the patient cannot stop the medication responsible for retrograde ejaculation or when the drug prescribed to produce anterograde ejaculation either has no effect or produces serious side effects, including dryness of the mucous membranes and hypertension.

Table 1 Drugs used to provoke ejaculation in cases of retrograde ejaculation

Drug	Dose
Imipramine	25 mg before intercourse or 25–75 mg/8 h
Midodrine	5 mg/8 h
Pseudoephedrine	60 mg every 6 h
Ephedrine	25–50 mg before intercourse or 10–15 mg four times day
Brompheniramine	8 mg/12 h

Sperm should be obtained in coordination with the partner's ovulation period. The urine should be alkalinized to obtain a pH of 7.2–7.8. In order to do this, the patient should take 1–2 g of sodium bicarbonate every 6 h, starting 48 h before intercourse, and then extract a sample of post-orgasm urine. The bladder may also be catheterized to instill 10–50 mL of a buffered medium suitable for sperm, such as F-10 or Ham's medium. The catheter is then removed and, after ejaculation, the patient is catheterized again to collect the intravesical contents, thus avoiding all contact between the sperm and the urine (Mahadevan et al., 1981). It is important to use non-spermicidal lubricants and urethral catheters not made of silicone in order to prevent sperm adhesion (Fode et al., 2012). If the product obtained is not of sufficient quality for intrauterine insemination (IUI), fresh semen should be used, or, alternatively, it should be frozen for use in in vitro techniques, such as intracytoplasmic sperm injection or ICSI. If none of the methods used is successful, sperm should be obtained directly from the testes (testicular sperm extraction or percutaneous sperm aspiration) or the epididymis (microsurgical sperm aspiration) for later use in assisted reproduction techniques.

Penile Vibratory Stimulation

This technique is intended to cause ejaculation by provoking sufficient stimulation through vibrations at the level of the frenulum in the glans of the penis. Patients who may benefit from this technique are those who have suffered a spinal cord injury, but who maintain the sacral afferents and efferent, the thoracolumbar sympathetic efferent fibers, and the communication between the sacrum and the thoracolumbar segment intact. In this sense, the ideal candidates are patients with a spinal cord injury above T10. The technique should be performed at least 6 months after the injury. Penile vibratory stimulation (PVS) produces reflex ejaculation in 94% of patients with a T1–T6 lesion and in 67% of patients with a T6–T12 lesion (Bird et al., 2001). Patients with lower spinal cord injuries who thus present with an altered arc reflex only have a 15% success rate with PVS (Sonksen, 2003). In patients in whom standard PVS has failed, the use of two vibrostimulators at the same time, one on the frenulum and one on the dorsal portion of the glans, can recover ejaculation in 22% of cases (Brackett et al., 2007). The vibration parameters are key to achieving an ejaculation. Sonksen et al. (1994) has determined that vibration amplitude of 2.5 mm at a frequency of 100 Hz is optimal for inducing ejaculation. The vibrator is placed on the frenulum until ejaculation occurs (Fig. 1). Previous administration of phosphodiesterase inhibitor drugs may be beneficial in achieving ejaculation following PVS (Giuliano et al., 2008). Midodrine (7.5 mg) may also be used 120 min before PVS. Vibration cycles are generally run for 2–3 min followed by 1 min of rest. Several cycles are repeated until ejaculation is achieved. The technique is considered to have failed when sperm have not been obtained in either of two separate PVS procedures performed at least 1 week apart. The ejaculate is collected in a sterile flask that can be used in different ways depending on the sperm parameters of the semen obtained. If there are more than 4 million mobile spermatozoa, either intravaginal insemination or IUI are good options because of their low cost and low invasiveness (Van Voorhis et al., 2001). Couples may also perform PVS at home. The procedure should coincide with the partner's ovulation as determined by means of the temperature method or with the aid of kits that measure LH in urine. The ejaculate thus obtained is injected into the vagina. This technique has a success rate of 25%–65% (Fode et al., 2012). The other option, IUI, must be

Fig. 1 Penile vibrator located on the frenulum.

performed in a doctor's office and is successful in one out of three couples in which the male has a spinal cord injury (Fode et al., 2012). Side effects of PVS include irritation of the glans and autonomic dysreflexia. Dysreflexia occurs mainly in patients with a spinal cord injury above T6. Any stimulus that causes a sympathetic discharge, including bladder distention, can cause this reaction. Symptoms include sweating, facial redness, bradycardia, and high blood pressure. If a blood pressure spike occurs during the procedure, it should be stopped immediately and the patient should be sat upright. If there is a previous history of autonomic dysreflexia, 20 mg of sublingual nifedipine should be administered 15 min before PVS (Steinberger et al., 1990). This procedure is contraindicated in patients with severe heart disease or untreated high blood pressure.

Electroejaculation

The only device approved for this technique is the Seager electroejaculator (Dalzell Medical Systems, The Plains, VA, USA) (Figs. 2 and 3). Transrectal electrical stimulation at the level of the prostate and the SVs leads to the patient ejaculating. As in PVS, autonomic dysreflexia may be triggered with this technique; therefore, the same procedures must be followed for prevention and treatment. The bladder must be emptied prior to the procedure and 40 mL of a special buffered substance, such as F10, should be administered. The patient is placed in the lateral decubitus position. A rectoscopy should then be performed to identify rectal lesions that would contraindicate the procedure. Other contraindications include the patient having a pacemaker or taking anticoagulants. At the end of the procedure, a final examination should be made to detect possible lesions caused by EEJ. During the procedure itself, the patient's heart rate and blood pressure should be monitored constantly. The probe of the electrostimulator is inserted into the rectum with the electrodes directed toward the prostate and SVs (Fig. 2). Stimulation is achieved with a wavy pattern. First, a 5 V current is applied for 5 s and then stopped abruptly, followed by a 20 s pause. The cycle is repeated (5 s of current, 20 s of rest), but increasing the current 1–5 V each time until reaching 20–30 V (Brackett et al., 2002; Fig. 3). The Seager electroejaculator determines the intrarectal temperature and will automatically stop the procedure if the temperature exceeds 38°C. The ejaculation will occur in either a projectile or a drooling fashion, making it necessary to press on the urethra (a technique called "milking"). At the end of the procedure, the patient should be probed to catch any retrograde ejaculation that may have reached the bladder. To this end, a non-spermicidal probe and non-spermicidal lubricant are used. EEJ is the method of choice for patients with low spinal cord injuries, flaccidity in the lower limbs, and/or absence of the bulbocavernosus reflex. Because these patients have altered sensitivity, it is not necessary to perform the procedure under general anesthesia. Patients with high spinal cord injuries in whom PVS has failed are also candidates for EEJ. If there is no rectal sensitivity and if autonomic dysreflexia can be reversed with nifedipine, the procedure can be performed without general anesthesia. In patients with cervical lesions or with a history of dysreflexia, EEJ should be performed under general anesthesia. With regard to results, the largest published series on the use of this procedure (Brackett et al., 2010) found that in 210 patients with spinal cord injuries who underwent EEJ a total of 953 times (a mean of 4.5 times per patient), sperm suitable for insemination or other, more complex techniques was obtained in 90% of the cases. However, EEJ is not only used for patients with spinal cord injuries. It has also been used, for example, for cryopreservation of semen in a pediatric population that is unable to masturbate or in patients who do not masturbate for cultural or religious reasons (Berookhim and Mulhall, 2014). It can also be used in patients who present with anejaculation after a retroperitoneal lymphadenectomy, where it has been shown to achieve good results (Hsiao et al., 2012).

Therapeutic Protocol for Obtaining Sperm

PVS should be the technique of choice. In cases of failure, EEJ can be performed. EEJ, together with IUI, is a cost-effective procedure if performed without general anesthesia (Ohl et al., 2001). However, in cases where anesthesia is required (e.g., in patients without spinal cord injuries, with incomplete or cervical lesions, or with a tendency to dysreflexia), IUI is not effective and in vitro

Fig. 2 Probes of the electrostimulator.

Fig. 3 Seager Model 14 electroejaculator.

fertilization (IVF) should be used. In this latter group of patients, it is thus more advisable to perform surgical extraction of sperm under local anesthesia and then to perform IVF through ICSI.

Conclusion

- In patients with ejaculatory disorders it is essential to know the patient's surgical history, which medications he is taking, and whether there are any underlying neurological or metabolic diseases.
- In patients with low seminal volume (< 1.5 mL), the presence of sperm in the urine after orgasm should be checked to rule out or confirm retrograde ejaculation.
- If there is low seminal volume and no retrograde ejaculation, a transrectal ultrasound should be performed to assess any obstruction of the ejaculatory ducts.
- Sympathomimetic drugs act at the level of the internal sphincter/bladder neck, thus favoring antegrade ejaculation.
- Vibratory stimulation of the penis is especially indicated in patients with high spinal cord injuries while EEJ is indicated in patients with low spinal cord injuries.

Erectile Dysfunction: Evaluation and Pathophysiology

Tolulope Bakare and Ramy Abou Ghayda, University of Illinois at Chicago, Chicago, IL, United States

Introduction

The National institute of health Consensus Development Conference on Impotence in 1992 defined male erectile dysfunction as the inability to achieve or maintain an erection sufficient for satisfactory sexual performance and vaginal intercourse ([NIH Consensus Conference, 1993](#)). The Massachusetts Male Aging Study (MMAS), an observational survey of non-institutionalized subjects, which became a landmark study in the field, found that in men aged 40–70 years, 52% of men reported that they were somehow affected by this problem, with different intensity ([Feldman et al., 1994](#)). A successful erection is only achieved and maintained by the interplay of complex interrelated psychological, vascular, hormonal and neurological processes ([Montague et al., 1996](#)). Normal sexual function in males entails of four stages: sexual desire or libido, erection, ejaculation and orgasm, and detumescence or penile flaccidity.

Penile Anatomy and Normal Physiology of Penile Erection

The penis is composed of two corpora cavernosa and the corpus spongiosum that surrounds the urethra; together they form a three cylindrical system. The tunica albuginea, a tough and thick sheath, surrounds and supports the erectile tissues and plays a major role in erection. It is composed of a bi-layer of collagen and elastic fibers. The inner circular layer contains the intercavernosal columns that prevent the corporal bodies from overexpansion. The outer longitudinal layers provide support and course the penis from its glans to its base at the proximal crura.

The internal iliac artery branches into the internal pudendal artery that constitutes the main arterial vascular supply. The internal pudendal artery in turn branches into the dorsal, bulbourethral, and cavernous arteries. The cavernous arteries supply the spongy trabecular tissues trapping the blood during erection.

The penile venous drainage is through subtunical venules and emissary veins exiting the tunica albuginea and draining the corporal bodies. These emissary veins unite to form circumflex, periurethral, and superficial dorsal veins ([Awad et al., 2010](#)).

The innervation of the penis is both autonomic and somatic. Autonomic innervation is through the spinal cord and peripheral ganglia and is composed of two elements. The sympathetic nerves arises from T11-L2, they travel in the pelvic nerves, mainly pudendal nerves. The parasympathetic nerves arise from S2-S4; they travel in the hypogastric nerves and end up in the pelvic plexus. Erection is thus stimulated by pelvic plexus and cavernous nerve and inhibited by the sympathetic trunk. The autonomic nerves merge to form the cavernous nerves. The motor and sensory nerves are primarily responsible for sensation and the contraction of the bulbocavernosus and ischiocavernosus muscles ([Dean and Lue, 2005](#)).

Erection starts by external stimulation. This stimulation will lead to secretion of nitric oxide (NO) from the nonadrenergicnon-cholinergic (NANC) endothelial nerve endings. The NO release will lead to the penile smooth muscle relaxation, increasing blood flow and reducing cavernosal arterioles resistance ([Musicki and Burnett, 2006](#)). Erection is achieved by the engorgement of the corpora cavernosa sinusoids with blood. The increase in shear stress contributes further to the erection through the secretion of NO by the penile tissue endothelium ([Burnett, 1995](#).) Detumescence occurs secondary to phosphodiesterases enzyme in degrading cGMP and cAMP.

Causes of ED

The causes of ED can be grouped into two main categories: psychogenic (due to stress, performance anxiety or other psychological disorders) or organic (hormonal, neurovascular, drug induced or anatomical etiologies) ([Table 1](#)). Many patients might present with a combination of both etiologies. Men suffering from psychogenic ED are usually younger in age and report a specific incidence

Table 1 Organic causes of ED

<i>Cause</i>	<i>Example</i>
Vasculogenic	Atherosclerosis, sinusoidal fibrosis
Neurogenic	Spinal cord injury, multiple sclerosis, pelvic surgeries
Endocrinological	Diabetes, hypogonadism, hyperprolactinaemia
Drug-induced	Antidepressant, antipsychotic, recreational drugs
Local factors	Penile fracture, Peyronie's disease
Systemic diseases	Renal failure, cardiovascular diseases

([Shamloul and Ghanem, 2013](#)).

Table 2 Common prescription drugs associated with ED

<i>Drug class</i>	<i>Example</i>
Cardiac drugs	Digoxin, Amiodarone
Diuretics	Spironolactone, Thiazide
Antihypertensives	Beta Blockers, Verapamil, Clonidine
Antidepressants	Selective serotonin reuptake inhibitors, Tricyclic antidepressants
Hormones	Antiandrogen, Ketoconazole, LH releasing hormones agonists
Histamine receptor 2 antagonists	Ranitidine, Cimetidine
Recreational drugs	Alcohol, marijuana, cocaine

(Muneer et al., 2014).

after which they developed ED. They typically have normal nocturnal and morning erections and normal erections during masturbation. Organic ED is any disturbance in the process or coordination of the neurovascular and biochemical/hormonal component responsible for the achievement of penile tumescence.

History and Physical Examination

Before any effective management for ED a thorough history must be obtained. The physician should start with obtaining a detailed past medical history, psychosocial history, surgical history, and a list of prescribed medications (Table 2). A thorough medical history should be asked including but not limited to diabetes, cardiovascular disease, and lower urinary tract symptoms. The focus should be then turned to trying to differentiate between organic versus psychogenic cause by determining the onset, duration, and course of dysfunction. Standardized questionnaire may be used to assess the intensity of the problems. The two most used and informative questionnaire are International Index of Erectile Function and the Sexual Health Inventory for Men (Rosen et al., 1999.) Because erectile dysfunction can be a strong predictor of cardiovascular disease, all men presenting with ED should be screened for any cardiac symptoms. Physical exam includes exam checking pulses and sensations, signs for any trauma or scars, secondary sex characteristics. A more focused genital exam should be done for penile size, fibrosis and elasticity, testicular size and consistency. Rectal exam is reserved for patients over 50.

Treatment

Patients with mild ED have been shown to benefit from life style modification of risk factors, like smoking cessation, prevention of obesity and regular exercise (Gupta et al., 2011.) Treatment options include phosphodiesterase 5 inhibitors that may be oral, intra-cavernosal or intraurethral. Other options include vacuum assisted devices, and penile surgery (Table 2).

Oral phosphodiesterase 5 inhibitors (PDE5I) are the first line treatment for erectile dysfunction. Phosphodiesterase type 5 inhibitors prevent the breakdown of cyclic guanosine monophosphate (cGMP) to GMP in the cavernosal smooth muscle. This way, the activity of cGMP is prolonged decreasing the intracellular calcium stores facilitating smooth muscle relaxation via nitric oxide in both cavernosal arteries and muscle and subsequent rigid erections (Shamloul and Ghanem, 2013.) They are considered safe although they are contraindicated in patients prescribed nitrates and patients in whom vasodilation is not advisable, because of the risk of severe hypotension.

The side effects are most of the time well tolerated by patients, with headaches and flushing being the most common (Eardley et al., 2010.)

Testosterone can be used to treat erectile dysfunction, but its use has been limited to hypogonadic patients suffering from ED. In patients with low testosterone concentrations dual therapy of PDE5I and testosterone has been studied with promising results (Jain et al., 2000.)

Yohimbine, considered to be a sexual enhancer, is thought to contain active ingredients that work as a presynaptic alpha 2 adrenoceptors antagonist in the brain and spinal cord. Side effects include tachycardia, blood pressure changes, hallucinations and dizziness. Even though the active metabolite of *Butea superba* is a butenine, its mechanism is still unclear till this day (Muneer et al., 2014.)

Intracavernosal and Intraurethral Therapy

They are considered second line therapy. Their use leads to a predictable and fast response. Patients self-inject them into the penile corpora cavernosa after a period of supervised training. Treatment consists most commonly of prostaglandins E1 analogue (alprostadil), other agents such as papaverine, phentolamine, and vasoactive intestinal polypeptide have been used. Their mechanism of action is to increase smooth cell relaxation by increase intracellular cyclic AMP. Therapy side effects include priapism and penile

fibrosis. Alprostadil is used in intraurethral therapy as a pellet. Reported side effects include penile and urethral pain and priapism (Shamloul and Ghanem, 2013.)

Vacuum Devices

Vacuum devices can be used alone or in combination of therapy. Their mechanism of action depends on the increasing blood flow to the corpora cavernosa with continuous negative suction. Side effects can be serious including skin necrosis, penile pain and numbness (Cookson and Nadig, 1993) These devices are not widely used because of patients discomfort and the unnatural approach to achieve erection.

Penile Surgery

Penile surgery, consisting of prosthesis implantation, is the third line of therapy for ED. It is reserved for patient with refractory ED failing all other available therapy. Its complications are rare but devastating, including infection and device malfunction (Carson et al., 2000.)

Orgasmic Dysfunction

Tolulope Bakare and Ramy Abou Ghayda, University of Illinois at Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

The American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders, 5th edition, DSM-V-TR, defined orgasmic disorders as a persistent or recurrent delay in, markedly reduced intensity, or absence of orgasm during a sexual experience. These symptoms must have been present for at least 6 months and occurs on at least 75% or more of sexual activity interactions and causing marked distress or interpersonal difficulty (Tobia, 2013). This definition gave the treating physicians the flexibility in judging and assessing women's orgasmic capacity based on the patient's socio-demographics and previous sexual experiences (Ishak et al., 2010). Of note this definition does not apply if the symptoms are caused directly and solely by an organic medical condition, a substance abuse or drug induced. This condition should not be accounted better by another Axis 1 disorders (other than sexual dysfunction disorders) like mood or anxiety disorders. The American Psychiatric Association subdivides further the disorder into lifelong type versus acquired type; generalized type versus situational type; and due to psychological factors versus due to combined factors (Tobia, 2013).

Evaluation

History and Physical Exam

A comprehensive review of sexual history is key element in establishing the diagnosis. The physician should take note of all the factors that could affect or cause orgasmic dysfunction, starting with patients' demographics (age, socio-cultural background), comorbidities (anatomical or physiologic), psychological history, history of physical or sexual abuse, prescribed medication, substance abuse to reach finally interpersonal relationship with the partners. The physician should next characterize the orgasmic dysfunction and build a detailed description of it. It is essential to differentiate orgasmic disorders from other sexual dysfunction like arousal or desire disorders (Lewis et al., 2004). Anatomical abnormalities that might cause orgasmic dysfunction (like lichen sclerosis) should be ruled out by a careful focused physical exam.

Laboratory Evaluation

Laboratory evaluation is usually not necessary in diagnosis or management of orgasmic disorders.

Male Orgasmic Disorder

Normal Ejaculation in Men

This complex reflex is dependent on the sympathetic thoracolumbar nerve fibers originating from T10 to L2 and somatic nerve fibers originating from S2 to S4. Mechanical stimulation of the glans penis sends somatic input to this reflex through the dorsal nerve of the penis. Higher cerebral centers have a vital input and play a role in coordination and achievement of ejaculation. These centers include the midbrains, thalamus and hypothalamus, and the cortex. (Giuliano and Clement, 2005). Before ejaculation happens, the contractions of the smooth muscles transport the sperm stored in the epididymis to the vas deferens. Sympathetic input leads then to the coordinated contraction of the vas deferens moving the sperm to the ejaculatory ducts reaching the seminal vesicles. The somatic nerve fibers cause rhythmic contractions of the pelvic and periurethral muscles carrying the sperm and its seminal plasma fluid into the urethra projecting it to the outside. Retrograde ejaculation is prohibited by the efferent sympathetic fibers input, T10–L2, leading to the closure of the bladder neck and opening of the external urethral sphincter (Thomas, 1983).

Male orgasmic disorders are part of the male sexual dysfunction, which include erectile dysfunction, premature ejaculation, delayed orgasm, and anorgasmia. Premature ejaculation (PE) is defined in the DSM V as the persistent or recurrent pattern of ejaculation occurring during partnered sexual activity within approximately 1 min following vaginal penetration and before the individual wishes it. This symptom must have been present for at least 6 months and must be experienced on almost all or all occasions of sexual activity. It causes clinically significant distress in the individual (Table 1). Delayed ejaculation (DE) is defined by a marked delay in ejaculation or a marked infrequency or absence of ejaculation on almost all or all occasions of partnered sexual activity without the individual desiring delay, persisting for at least 6 months and causing significant distress to the individual (American Psychiatric Association, 2013). Anorgasmia is defined as the perceived absence of orgasm, independent of the presence of ejaculation.

Table 1 Classification of PE

<i>Premature ejaculation subtype</i>	<i>Possible underlying causes</i>
Lifelong	Biological or functional disturbances
Acquired	Medical and/or psychological disturbances
Variable	Normal variant
Subjective	Cultural beliefs or social misconceptions

From: McMahon, C., Abdo, C., Incrocci, L. (2004). Disorders of orgasm and ejaculation in men. *The Journal of Sexual Medicine* 1, 58–64.

Etiologies of Orgasmic Disorder May be Organic or Psychogenic

Organic Etiologies of Male Orgasmic Disorders

Spinal cord injuries are the main organic cause leading to male orgasmic disorders.

These injuries are responsible for the disruption of either the sympathetic and/or parasympathetic input. Iatrogenic injury of these nerves during pelvic or retroperitoneal surgery also may contribute to the interruption of neurogenic impulses responsible for orgasm (Maizels, 1998). Diseases affecting the peripheral nervous system, like multiple sclerosis and diabetes mellitus also play a causative role in orgasmic dysfunction. Medications that may lead to orgasmic dysfunction in the male, including antipsychotic, antidepressant, and antihypertensive (McMahon et al., 2004).

Psychogenic Etiologies of Male Orgasmic Disorders

Most of the literature consists of expert opinion or case reports. Perelman's theory blames some masturbation habits leading to the patient's preference for masturbation over other sexual experience and intercourse (Rowland et al., 2004). Other theories include discrepancy between the male sexual fantasies and their reality, or the excessive concerns with partner sexual pleasure (Rowland et al., 2004). Some psychological etiologies of delayed ejaculation may include sexual performance anxiety, a history of sexual abuse or sexual trauma during childhood, repressive sexual education or religious constraints (Jenkins and Mulhall, 2015). Hypothetical etiologies include substance abuse, obesity and psychological disorders.

Management of Male Orgasmic Disorder

Studies have shown that while treating PE, combining pharmacotherapy and psychotherapy is superior as an intervention to drugs alone. The gold standard in PE pharmacological therapy is selective serotonin reuptake inhibitors, which are used off label, such as dapoxetine. Other safe drugs exist with less efficacy including local anesthetics, tramadol, phosphodiesterase inhibitors, and alpha-1 adrenoceptors antagonists (Abdel-Hamid et al., 2016). Multiple drug treatment have been used for DE including alpha 1 adrenergic receptors agonists, psychotropic medications, oxytocin and Bethanechol (Abdel-Hamid et al., 2016).

Female Orgasmic Dysfunction

Normal Ejaculation in Women

Women's orgasm is achieved by erotic stimulation of either genital, non-genital sites, or both. In the female brain, multiple areas are responsible for integration and regulation of orgasm, including the paraventricular nucleus of the hypothalamus, the periaqueductal gray region of the midbrain, the hippocampus, and the cerebellum (Meston et al., 2004). In orgasmic dysfunction central and peripheral pathophysiology have been involved. The sympathetic nervous system activation increased vaginal impulse amplitude and blood flow in response to erotic stimulation in normal patients and patients with altered sexual desires, but not for patients with anorgasmia (Meston and Gorzalka, 1996). The pudendal nerve transmits clitoral stimulation to the spinal cord and the brain, on the other hand vaginal stimulation are transmitted via pudendal, hypogastric, and pelvic nerves. The vagus nerve has been showed to provide an alternative orgasmic pathway, bypassing spinal cord control (Meston et al., 2004).

Etiologies of Female Orgasmic Disorder

Many of the general medical condition that affects the patients' quality of life or mental wellbeing are associated with sexual dysfunction. Orgasmic disorders have been reported in multiple sclerosis, chronic kidney diseases, fibromyalgia, and atherosclerosis. Anatomic pelvic pathologies and pelvic surgeries have lead to orgasmic disorders; this has been demonstrated in patients with stress urinary incontinence and patients who underwent hysterectomy.

Table 2 Possible treatment for female orgasmic dysfunction

<i>Treatment</i>	<i>Possible benefit</i>
Hormone replacement therapy Tibolone	Promising results in post-menopausal women
Partial androgen replacement using testosterone	Used in anorgasmic post-menopausal women
Phosphodiesterase inhibitors	Mixed results
Oxytocin and midodrine	Promising results
Bremelanotide	Effective but with adverse side effects
Eros-Clitoral device	Only FDA approved treatment

From: Ishak, W. W., Bokarius, A., Jeffrey, J. K., Davis, M. C., & Bakhta, Y. Disorders of orgasm in women: A literature review of etiology and current treatments. *The Journal of Sexual Medicine*, 7(10), 3254–3268.

Drug induced orgasmic disorders is very often seen, and it is caused by the side effects of these medications. The most culprits ones are the psychotropic drugs. Stimmel et al. reported anorgasmia in almost one third of patients prescribed selective serotonin reuptake inhibitors (SSRIs) (Stimmel and Gutierrez, 2006). It has been found that these side effects on orgasmic dysfunction are directly related to the dosage of the medication. Although moderate alcohol consumption have a sexually stimulant effect, heavy consumption was correlated to orgasmic dysfunction. Hormonal abnormalities or changes during menopause have been associated with orgasmic disorders. Orgasmic dysfunction can have a genetic factor. In a study done by Dunn et al. it was found that difficulty-achieving orgasm was hereditary in about 34%–45% depending on the nature of the sexual experience (Dunn et al., 2005).

The psychosocial aspect plays a major role in orgasmic disorders. Body and genital image contribute to orgasmic dysfunction (Ackard et al., 2000). Anorgasmia has been linked to negative experience and feelings of desperation among women who suffers from this condition. A history of previous sexual abuse may also cause generalized feeling of sexual dissatisfaction and higher incidence of orgasmic dysfunction. Socio-demographics factors may also play an important role in contributing to orgasmic disorders, with education, social status and age being among the most important factors (Meston et al., 2004).

Orgasmic dysfunction is the second most common reported sexual dysfunction in women. Because women and couples are reluctant and embarrassed to discuss sexual issues, orgasmic disorders are under-reported and rarely addressed despite its hypothetical high prevalence. It is thus the responsibility of the treating physician to always assess patient's sexual function. Assessment instruments and questionnaire can help the physicians in their evaluation.

Management of Female Orgasmic Dysfunction

Only few clinical trials have studies efficient and reproducible medical therapy for orgasmic disorders in women, and the FDA has not approved any to this date. The physicians have both psychological and pharmacological intervention to intervene. Some of these interventions are extrapolated from treatment of other female sexual disorders (Table 2.) In postmenopausal women, hormone replacement therapy has shown promising results in restoring orgasm (Basson, 1999). In patients with drug induced orgasmic disorders, stopping these medication, switching to a different family of drugs with less sexual disorder side effect or using strategies like drug holidays and adjunct therapy are all possible approaches (Stimmel and Gutierrez, 2006). Buspirone and Yohimbine have been used as adjunct therapy or as SSRI therapy replacement (Basson, 1999). Although they cause less sexual dysfunction side effects, their benefit on orgasmic dysfunction is controversial. Bremelanotide, a melanocortin 1 and 4 receptor agonist, has been demonstrated to increase orgasm score measured by standardized questionnaires, and was concluded to be effective therapy (Safarinejad, 2008). The drug was not approved because it caused of elevated blood pressure. Dietary supplements and natural remedies have been shown to be beneficial in some studies, even though they lack universal approval regarding efficiency and safety.

The FDA has only approved the Eros-Clitoral device for the treatment for the female orgasmic disorder. This device increases the clitoral blood flow by gentle vacuum.

A short-term therapy with cognitive behavioral therapy can lead to a more positive thoughts regarding sexuality and subsequently increase orgasm (Heiman, 2000). Examples of such therapies include directed masturbation and sensate focus exercises. It has been well established that masturbation plays a beneficial role in women suffering from orgasmic dysfunction, and these women had a higher chance of achieving orgasm than non-masturbators (Struck and Ventegodt, 2008). Kegel exercise have been studies with mixed results, with the most benefit found in female suffering with additional urinary incontinence and women not suffering from the psychological etiology of orgasmic disorders (Ishak et al., 2010).

Glossary

Hypogonadism A condition in which the production of sex hormones and germ cells is inadequate.

Hypothalamus The part of the brain situated below the thalamus which functions to regulate body temperature, metabolic processes, and other autonomic activities. The hypothalamus produces gonadotropin-releasing hormone (GnRH) which plays an important role in fertility.

In vitro fertilization A procedure in which eggs from a woman's ovaries are retrieved, fertilized with sperm in a laboratory, and then transferred back to the uterus as an embryo.

Metabolic syndrome A group of metabolic risk factors linked to insulin resistance and associated with increased risk of cardiovascular disease. Components of the diagnosis include increased waist circumference, elevated triglycerides, low HDL cholesterol, hypertension, and impaired fasting glucose.

Pituitary gland A small endocrine gland attached to the base of the brain, consisting of an anterior and a posterior lobe. The pituitary gland releases luteinizing hormone (LH) and follicle-stimulating hormone (FSH) which assist in reproductive function.

Primary testicular failure A congenital, developmental or genetic defect in sperm production by the seminiferous tubules, which may be complete or partial.

Sperm morphology A parameter assessed during semen analysis that measures the percentage of sperm with a normal appearance.

Sperm motility A parameter assessed as part of a semen analysis that measures the ability of sperm to swim in a forward direction.

Vas deferens The duct through which semen is carried from the epididymis of each testicle to an ejaculatory duct.

Background

Among infertile couples, approximately 20% of cases can be attributed solely to an abnormality in the male partner. Male factor infertility is also identified as a contributing factor in up to 50% of infertile couples ([American Society for Reproductive Medicine, 2015](#)). There are multiple causes for male infertility, including blockage or absence of the vas deferens, problems related to the hypothalamus or pituitary gland, primary testicular failure, and dysfunction of the seminiferous tubules. Male infertility may also result from serious underlying medical conditions. Causes of male infertility may be either congenital or acquired. Unfortunately, an identifiable cause for male infertility is not always present, with approximately 40%–50% of male infertility cases being classified as idiopathic or unexplained ([Fritz and Speroff, 2011](#)).

The primary test to achieve a diagnosis of male factor infertility is a semen analysis. This test involves collection of a semen sample followed by laboratory evaluation of sample volume, concentration, motility, and morphology. Clinical values have been established to categorize men as either fertile or subfertile based on semen analysis findings. Men with abnormal semen analysis parameters generally undergo further medical evaluation to characterize the exact nature of the problem.

While the majority of infertile men present to fertility specialists solely for evaluation and treatment of their reproductive issues, there is increasing evidence that a diagnosis of infertility has a broader health impact that must also be addressed. Comorbidities associated with male infertility may not only influence a man's ability to father a child, but also his life expectancy and overall well-being ([Ventimiglia et al., 2016](#)). One of the challenges with evaluating associations between infertility and comorbid health conditions is that the diagnosis of many health conditions may be chronologically separate from the diagnosis of infertility. However, the trend toward delaying fatherhood in many Western countries may result in more men who present for an infertility evaluation with concomitant medical conditions with a known detrimental effect on fertility ([Ventimiglia et al., 2016](#)). When evaluating associations between infertility and comorbidities, confounding factors such as obesity and smoking are known to negatively impact both semen quality and overall health. This can make it difficult to identify causal relationships and draw definitive conclusions from data. Nevertheless, research is ongoing to evaluate specific health risks that infertile men may face later in life ([Ventimiglia et al., 2015](#)). The idea that semen analysis parameters may be used as a biomarker of overall health or a predictor of mortality is gaining acceptance as understanding of this topic increases. See [Table 1](#) for a list of key studies evaluating the relationship between male infertility and somatic health.

The general health status of men with infertility appears to be poorer than their fertile counterparts. Male infertility has been associated with higher rates of urogenital infections, autoimmune diseases, metabolic disorders such as diabetes, chronic kidney disease, and liver disease. Men with infertility are also at higher risk of developing ischemic heart disease, alcohol abuse,

Comorbidities and male infertility: a worrisome picture	Ventimiglia et al.	2016	Age, multiple comorbidities	<i>Current Opinion in Urology</i>

and drug abuse (Eisenberg et al., 2014). Associations between a diagnosis of male infertility and other negative health outcomes are strongest in men who undergo long term follow-up, emphasizing the fact that a comorbid diagnosis may come several years after an initial diagnosis of infertility (Eisenberg et al., 2014). Whether there is a cause and effect relationship between infertility and specific disease processes remains unclear, but recent data seem to indicate that men with infertility would benefit from discussions and interventions related to overall health. To date, exact mechanisms to explain connections between somatic health issues and infertility are lacking. However, approximately 15% of the male genome is involved in reproduction, so it is plausible that defects resulting in many health conditions may be linked to problems with fertility (Craig et al., 2017).

Health Risks Associated With Klinefelter Syndrome

As noted previously, causes of male factor infertility may be either congenital or acquired. Table 2 demonstrates somatic health risks in men with certain acquired forms of male infertility. One of the most commonly encountered congenital forms of male infertility is a genetic abnormality known as Klinefelter syndrome. Klinefelter syndrome is one of the most common causes of primary testicular failure, affecting approximately 1 in 1000 males. This disease process results from an additional X chromosome in men, mostly commonly presenting as a 47,XXY karyotype. Men with this condition generally have severely reduced sperm counts and underdeveloped testes. This abnormality is associated with significant health comorbidity and a life expectancy which is shortened by somewhere between 2 and 5 years. Men with Klinefelter syndrome are at increased risk to develop cerebrovascular disease which can ultimately lead to a stroke. Cardiovascular congenital anomalies such as aortic valve disease are also more prevalent in men with this condition. Incidence of thrombotic clots and leg ulcers appears to be elevated in men with Klinefelter syndrome, and they appear to have an increased risk of developing endocrine or metabolic diseases such as obesity, type 2 diabetes, and metabolic syndrome. Cardiovascular health may be at least partially improved with testosterone replacement therapy, although the effect of testosterone therapy leading to long term improvement in health outcomes remains a topic

Table 2 Somatic health risks associated with congenital causes of male infertility

<i>Congenital causes of infertility</i>	<i>Somatic health risks</i>
Klinefelter syndrome (primary testicular failure)	Cerebrovascular disease and stroke Shortened lifespan Valvular heart disease (aortic) Obesity Type 2 diabetes Metabolic syndrome Thrombotic clots Ulcers of the extremities Psychosocial and behavior problems
Congenital bilateral absence of the vas deferens	Variable manifestations of cystic fibrosis Pulmonary disease Pancreatic insufficiency and diabetes Malnutrition Sinusitis and bronchitis
Kallman syndrome	Cryptorchidism Testicular tumors
Cryptorchidism	Testicular cancer
Dermatologic syndromes ^a	DeSanctis Cacchione—retarded growth and sexual development, mental retardation, deafness, ataxia, quadraparesis Poikiloderma Congenitale—cataracts, bone defects, hypogonadism, hair growth defects, osteosarcoma H syndrome—heart anomalies, hyperpigmentation, hypertrichosis, short stature, hepatosplenomegaly, insulin dependent diabetes Ichthyosis—diabetes, cholesterol metabolism problems, limb defects

^aOther rare skin disorders which have a negative impact on fertility have also been documented.

of debate (Calogero et al., 2017). Men with Klinefelter syndrome may also suffer from psychosocial morbidity and behavior problems, with specific challenges such as lack of insight, poor judgment and impaired ability to learn from adverse experience. Long term testosterone replacement therapy does appear to be beneficial in this specific population to reduce psychologic and behavior issues (Simm and Zacharin, 2006).

Absence of the Vas Deferens

Congenital or acquired abnormalities of the vas deferens can cause obstruction in normal sperm transport. Approximately 1%–2% of infertile men are found to have congenital bilateral absence of the vas deferens. This finding is nearly universally related to mutations in the gene responsible for cystic fibrosis (CFTR gene). Interestingly, many men who are diagnosed with infertility related to abnormalities within the CFTR gene do not display the classic respiratory and pancreatic manifestations that are typical with cystic fibrosis. More than 95% of patients with cystic fibrosis are infertile, and in patients with clinically significant disease, progressive obstructive lung disease with bronchiectasis, frequent hospitalizations for pulmonary infections, pancreatic insufficiency, malnutrition, recurrent sinusitis, and bronchitis are common. In patients with outright cystic fibrosis, diabetes related to pancreatic failure typically results (Fritz and Speroff, 2011). Men with absence of the vas deferens who desire pregnancy require assisted reproductive technology which involves extraction of sperm or testicular tissue to obtain sperm cells which are then used in fertilization.

The Relationship Between Infertility and Malignancy

With nearly 40%–50% of cases of male infertility falling into the unexplained or idiopathic category, it is not uncommon for otherwise healthy individuals to be diagnosed with infertility. It is important to recognize that despite the overall healthy nature of these men, the diagnosis of infertility may place them at increased risk for comorbidities in the future (Eisenberg et al., 2016a). Table 3 outlines specific health risks that men with acquired infertility face.

Early studies evaluating connections between infertility and health outcomes focused primarily on cancer, with rates of specific types of cancer found to be increased in infertile men compared to the general population. The association between infertility and testicular cancer has been well-documented in multiple studies conducted in Europe and United States. Testicular cancer incidence is somewhere between 3 and 20 times greater in men with abnormal semen analysis parameters when compared with men from the general population who were matched for age and race (Eisenberg et al., 2016a). Males with abnormalities of testosterone

Table 3 Somatic health risks associated with acquired causes of male infertility

<i>Acquired causes of infertility</i>	<i>Somatic health risks and reproductive impact</i>
Generalized male infertility	Increased rates of malignancy: testicular cancer, colorectal cancer, melanoma, prostate cancer Increased rates of cardiovascular disease: stroke, myocardial infarction, peripheral vascular disease, cardiac mortality Increased rates of drug and alcohol abuse Increased rates of depression, anxiety, certain psychologic disorders Increased risk of obesity, diabetes, and metabolic syndrome
Obesity	Diabetes or insulin resistance Hyperlipidemia Hypercholesterolemia Hypertension Peripheral vascular disease Abnormal testicular thermoregulation Decreased testosterone synthesis Erectile dysfunction Decreased quality of sperm Increased sperm DNA fragmentation
Obstructive sleep apnea	Decreased luteinizing hormone (LH) production Higher rates of infertility Decreased serum testosterone
Environmental factors	Smoking: lung cancer, coronary heart disease, heart attack, stroke, peripheral vascular disease, cerebrovascular disease Alcohol abuse: liver cirrhosis, hypertension, coronary heart disease, stroke, gastrointestinal cancer Drug abuse: various negative health impacts depending on specific drug
Cardiovascular disease	Hypertension Peripheral vascular disease Non-ischemic heart disease Increased cardiovascular mortality
Dermatologic problems	Negative health impact associated with specific cause of dermatologic disease: relationship seen between infertility and skin disorders related to sarcoidosis, zinc deficiency, HIV, leprosy, erythema nodosum leprosum, and other specific disorders

production such as Kallman syndrome are known to have higher rates of cryptorchidism, or failure of testicular descent during fetal development. The failure of the testes to descend can either be unilateral or bilateral and is associated with impaired sperm production and increased rates of testicular tumors and cancer. However, even in men with normal testicular descent, a diagnosis of infertility still conveys an elevated risk of testicular cancer ([Fritz and Speroff, 2011](#)). While data is less convincing for other types of malignancy, rates of colorectal cancer, melanoma, and prostate cancer may also be elevated in infertile men.

Metabolic Syndrome and Infertility

The link between infertility and the metabolic syndrome has been heavily researched, with components of the metabolic syndrome consistently found to result in impaired fertility. Men who have been diagnosed with insulin resistance and diabetes have been shown to have higher rates of abnormal semen parameters, erectile dysfunction, and difficulty with ejaculation. Men who present to a physician due to issues with infertility also appear to have higher rates of baseline diabetes than the general population. Hyperlipidemia is more common in men with infertility, and elevated body mass index correlates with impaired semen production. Evaluation of men with hypertension, peripheral vascular disease, and nonischemic heart disease also demonstrates increased rates of abnormal semen parameters. Diabetes, hyperlipidemia, obesity, and hypertensive disorders are strongly associated with increased cardiovascular mortality ([Glazer et al., 2017](#)). The severity of the comorbid disease process appears to be inversely correlated with sperm quality. Hormonal, developmental, lifestyle, and genetic factors have all been proposed as explanations for the associations described earlier. However, it is important to remember that the majority of men presenting for an initial fertility workup are relatively young and may not carry diagnoses associated with the metabolic syndrome. While a current diagnosis of diabetes, hypertension, hyperlipidemia, or cardiovascular disease will have an immediate negative impact on a man's sperm quality, the majority of men with infertility will not meet diagnostic criteria for the metabolic syndrome at the time of their infertility presentation. Exact elevations in risk have not been clarified for each of these disease processes, but the risk that an infertile man will develop conditions such as diabetes, hyperlipidemia, obesity, or hypertension later in life appears to be elevated. The correlation between male infertility and a subsequent diagnosis of diabetes has been one of the areas which has undergone substantial research, with a reported 30% increased risk of developing diabetes later in life among infertile men compared to the baseline population ([Craig et al., 2017](#)).

The Impact of Obesity on Fertility

The topic of obesity as it relates to infertility warrants detailed discussion due to the widespread nature of obesity. Rates of obesity among reproductive aged men have tripled in the United States since the 1970s. Currently, greater than 33% of the population over 20 years of age are considered obese. The negative impact of obesity on male fertility is clear, with worsening rates of male fertility seen as body mass index increases. Obese men are at greater risk to develop hypogonadism, impaired sperm development, and erectile dysfunction. Disease states which are associated with obesity, such as sleep apnea and diabetes, may also lead to abnormalities within the endocrine system that can affect testosterone levels within the testicles. In the United States, approximately 3.4% of the population is affected by both obesity and diabetes. High levels of intratesticular testosterone are necessary for normal sperm production, so even small decreases in serum testosterone that are seen in obese men can result in drastic drops in levels of intratesticular testosterone. The mechanism for lower levels of testosterone in obese men is related to increased conversion of testosterone to estradiol and estrone, which are forms of estrogen. Adipocytes, which are the fat cells within the body, appear to play a key role in this conversion of testosterone to various types of estrogen. With higher fat stores, more testosterone is converted to estrogen, altering the overall testosterone levels of obese men (Craig et al., 2017).

Sleep apnea, a common problem seen in obese men, leads to fragmentation of the normal sleep cycle. Lack of proper sleep can decrease nocturnal production of luteinizing hormone (LH). LH is required for the production of normal circulating testosterone levels, and in men with sleep apnea, drops in circulating testosterone may lead to impaired fertility. Increased lower abdominal fat, thigh fat, and scrotal fat may also act as insulators of the testicles and impair normal testicular thermoregulation. With impaired thermoregulation of the testicles, testosterone synthesis as well as spermatogenesis are negatively affected. The ability to maintain an erection is necessary to achieve spontaneous conception, and obesity is unfortunately strongly correlated with erectile dysfunction. Of men who report erectile dysfunction, 79% are obese (Craig et al., 2017). The cause of erectile dysfunction in obese men is multifactorial, but decreased testosterone levels as well as increased inflammatory cytokines such as tumor necrosis factor alpha and interleukin 6 are believed to play a role in disrupting normal vascular function required to maintain a penile erection. Obesity appears to have a direct effect on the quality of sperm produced as well. Obese men are at higher risk to have lower sperm counts, lower numbers of progressive motile sperm, and elevated rates of sperm DNA fragmentation. High rates of sperm DNA fragmentation are associated with a worsened functional status of the sperm (Craig et al., 2017).

A Possible Association Between Dermatologic Conditions and Infertility

A correlation has been proposed between certain skin diseases and higher rates of semen abnormalities. While this correlation has not been studied extensively in the scientific literature, it appears that certain acquired skin diseases may have a negative impact on sperm quality, predominantly as the result of orchitis or epididymal obstruction. Acquired infections with dermatologic manifestations that have been correlated with diminished fertility include leprosy, HIV, erythema nodosum leprosum, sarcoidosis, Langerhans cell histiocytosis, and zinc deficiency. Medications such as methotrexate, spironolactone, and finasteride which are used to treat various dermatologic conditions and autoimmune diseases may also contribute to impaired fertility in men with skin disorders. Numerous congenital dermatologic syndromes (De Santis Cacchione syndrome, poikiloderma congenital, H syndrome, ichthyosis, and others) have also been correlated with diminished male fertility (Abdel-Naser and Zouboulis, 2016). While data is relatively sparse, this connection is worth mentioning since more information may become available in the future.

The Impact of Infertility on Offspring

It is becoming increasingly apparent that there are health risks associated with male factor infertility which may extend to the offspring of infertile men. Table 4 outlines specific effects of various comorbidities on the health of offspring. Awareness of this fact is important in the counseling of men who present for an infertility consultation. The study of epigenetics has led to interest in whether disease states or environmental exposures within an individual may have detrimental effects on future generations. In the case of obesity, the children of obese fathers may be predisposed to abnormalities related to reproductive function. Animal models have demonstrated altered metabolic function as well as increased rates of sperm abnormalities in the offspring of obese fathers (Craig et al., 2017). Human data is less prevalent, but early findings suggest that obesity within a father may lead to detrimental changes in sperm function, embryogenesis, and possibly overall health in future generations.

There also appears to be a complex relationship between male infertility and congenital malformations in offspring. Research from a large population database demonstrated an increased risk of death due to congenital malformations in first degree relatives of men who underwent semen analysis as part of an infertility work-up. While some of this increased risk may be attributed to the female partner, infertility within couples seems to result in increased risks to future offspring. Importantly, a correlation between semen quality and childhood cancer mortality in offspring has not been established (Hanson et al., 2017). When determining how to prevent health consequences for future generations, management of disease processes within the infertile patient appears to hold promise. For example, studies evaluating children born before and after maternal gastrointestinal bypass surgery for obesity demonstrated significant differences in receptor signaling for insulin, leptin, and other glucoregulatory pathways within the two groups of children. Improvements in endocrine function were noted in the group born to mothers who had previously undergone

Table 4 Familial health risks associated with male infertility

Medical comorbidity/intervention	Effect on offspring or reproductive outcomes
Paternal obesity	• Alterations in DNA methylation at the insulin-like growth factor 2 gene in newborns • Worsened epigenetic profiles in metabolic genes of offspring • Metabolic derangements in offspring
Poor semen quality	• No apparent increase in cancer risk to offspring
Male infertility	• Possible increased risk of death in offspring due to congenital malformations
Maternal gastric bypass surgery for obesity	• Improvements in receptor signaling for insulin, leptin, and glucoregulatory pathways seen up to 18 years after conception • Improvements in endocrine function of offspring
Paternal mental health disorders	• Children born at earlier gestational age
Nervous system diseases	• Lower average pregnancy rates with assisted reproductive technology (23% vs. 30%) • Lower live birth rates (15% vs. 23%)
Paternal endocrine disorders	• Lower birth weights of offspring (2970 g vs. 3210 g)
Paternal respiratory diseases	• Lower fertilization rates with assisted reproductive technology (61% vs. 64%)
Paternal musculoskeletal diseases	• Lower fertilization rates with assisted reproductive technology (61% vs. 64%)

gastric bypass surgery (Craig et al., 2017). More research is necessary in this area, but if specific disease processes result in impaired health for offspring, correction of the disease process prior to conception may eliminate a substantial health burden for future generations.

Assisted Reproductive Technology Outcomes

Many men with a diagnosis of infertility ultimately receive treatment with assisted reproductive technology in order to achieve pregnancies with their partners. Techniques such as in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) have been utilized to overcome various types of male infertility. There is an increasing body of data suggesting that women with comorbid conditions such as obesity, diabetes, and thyroid disease may have lower rates of success with assisted reproductive technology. Comparatively less is known about the impact of comorbid conditions on assisted reproductive outcomes in male patients. The male contribution to assisted reproductive technology has historically been minimized, but increased attention is being placed on the role of sperm in assisted reproduction in order to optimize fertility outcomes. Evaluation of fertilization and pregnancy rates following the use of assisted reproductive technology in infertile men with specific comorbidities has offered insight into the impact that these conditions have on the ability to achieve pregnancy with medical assistance.

Based on emerging data, possible relationships do exist between overall male health and success rates with IVF. In men with neurologic diseases, lower pregnancy rates and lower live birth rates have been demonstrated following IVF cycles. Lower fertilization rates were also seen in men with respiratory diseases and musculoskeletal diseases. Men with disorders of the endocrine system appeared to father smaller children compared to men undergoing IVF without an endocrine abnormality, and men with psychiatric disease or mental health disorders appeared to have children born at an earlier gestational age. Assisted reproduction cycles of obese men appear to have higher rates of miscarriage and lower clinical pregnancy and live birth rates. Specifically in obese men, the use of ICSI to achieve pregnancy may mitigate some of these poor outcomes (Eisenberg et al., 2016b). Refer to Table 4 for a summary of the impact of comorbidities on assisted reproductive outcomes. To date, the exact cause for these poor obstetrical outcomes remains unknown and data remains somewhat controversial. Future research will hopefully provide meaningful information regarding whether treatment or adequate management of underlying comorbid conditions can reduce negative reproductive outcomes in men who undergo interventions with assisted reproductive technology.

Glossary

Atherosclerosis Arteriosclerotic vascular disease, commonly known as a “hardening” of arteries. Due to chronic inflammation, arterial wall thickens and ultimately results in a plaque formation. Chronically enlarging plaque leads to lumen obstruction and eventual decreased supply of blood to downstream tissues, further resulting in chronic ischemia. Same plaque may rupture and result in a sudden obstruction of the blood vessel, resulting in tissue infarction (death). Most commonly, this process is encountered during a heart attack (myocardial infarction) or a stroke.

Corpus cavernosum Cavernous body of the penis which forms a paired structure (corpora cavernosa) and runs along the length of the penis from the pubic bone to the glans penis. The corpora are comprised of a spongy erectile tissue divided by the connective tissue, forming hollow “caverns” throughout. During erection, muscles in the trabecular septa relax, the spongy tissue fills with blood and the corpora enlarge in length and girth, further “trapping” the blood and resulting in penile erection.

Externa Outermost layer of a blood vessel, also known as adventitia. Composed of collagen fibers.

Hemoglobin A1c Also known as glycated hemoglobin is a form of hemoglobin measured to identify the 3-month average plasma glucose concentration. This blood test is used to evaluate glycemic control over the previous 3 months. In diabetes mellitus, higher levels of glycated hemoglobin correspond to a poorer control of blood glucose levels.

Intima Innermost layer lining a blood vessel. It is composed of a layer of endothelial cells supported by a connective tissue (internal elastic lamina) and comes in direct contact with the blood flow.

Media Middle layer of a blood vessel. It lies between the intima and the externa and is composed of smooth muscle fibers and elastic supportive tissue.

Nitric oxide synthase (NOS) Enzyme catalyzing production of nitric oxide from L-arginine. In mammals, it exists as three isoforms: neuronal NOS (nNOS) expressed in neurons, endothelial NOS (eNOS) expressed in endothelial cells, and inducible NOS (iNOS) present in all cell types. All three NOS isoforms have been identified in the corpus cavernosum, with nNOS responsible for initiation and eNOS sustaining erection.

Introduction

Erectile dysfunction (ED), defined as the consistent inability to achieve or maintain penile erection sufficient for satisfactory sexual intercourse, is a common condition in aging men and significantly affects their quality of life (Anon, 1993). This condition has been reported to afflict 52% of male adults between 40 and 70 years of age in the United States and about 322 million men worldwide (Aytac et al., 1999; Johannes et al., 2000). As its incidence increases with each decade of life, and the average duration of life has been progressively increasing, a corresponding increase in the number of men reporting ED should also be expected.

ED was previously believed to be mainly of psychogenic origin. Currently, comorbidities such as cardiovascular disease, diabetes mellitus (DM), hypertension, dyslipidemia, hypogonadism, lower urinary tract symptoms (LUTS), metabolic syndrome, and depression have been described as primary risk factors for the development of ED. Additionally, modifiable lifestyle factors, including physical inactivity, smoking, alcohol consumption, poor diabetes control, and obesity, have been associated with ED. A fine balance between comorbid conditions and lifestyle modification must be carefully maintained in order to prevent or improve ED (Fig. 1).

Comorbidities

Aging

Aging is a well-established risk factor for development and severity of ED. This relationship has been previously demonstrated in several epidemiological studies, to include the Baltimore Longitudinal Study of Aging and the Massachusetts Male Aging Study (Shock et al., 1984; Feldman et al., 1994). According to the Rancho Bernardo Study, ED increases from 16% in men younger than 50 years to >71% in men who are 70 years or older (Barrett-Connor, 2005). Aging may affect all the components of the erectile process, including nerves, arteries, veins, cavernosal tissue, and the hormonal milieu.

Benign Prostatic Hyperplasia/Lower Urinary Tract Symptoms

LUTS associated with benign prostatic hyperplasia (BPH) and ED are highly prevalent in older men. Evidence suggests that both may have a common pathophysiology. Several epidemiological studies report that LUTS/BPH and their negative impact on quality

Fig. 1 Erectile function as balance between comorbidities and risk factor modification.

of life are independent risk factors for the development or exacerbation of ED. Moreover, quality of life indices reported by patients are significantly worse in those with simultaneous LUTS/BPH and ED. Experimental receptor mapping studies and animal models of bladder outlet obstruction support the hypothesis that LUTS/BPH partially results from increased sympathetic tone in the pelvis. This further results in down-regulation of corporal smooth muscles, thus impairing erections (Kobayashi et al., 2011; Lin et al., 2012).

The development of BPH has been linked to the systemic dysfunction represented by the metabolic syndrome. Prostate growth has been correlated with glucose intolerance (elevated plasma insulin levels and presence of noninsulin-dependent diabetes), central obesity/elevated body mass index (BMI), hypertension and dyslipidemia. Since all the processes representing the metabolic syndrome are associated with endothelial damage and dysfunction, they further provide a valid causal link between LUTS and ED (Barbosa et al., 2013).

Atherosclerosis and Cardiovascular Disease

The process of atherosclerosis begins in childhood, remains asymptomatic through early adulthood and becomes clinically evident in middle age. Endothelial dysfunction represents the initial, early phase of atherosclerosis. During this phase, the bioavailability of vasodilators, mainly nitric oxide (NO), decreases, shifting the balance in favor of endothelial vasoconstrictors. During the intermediate phase, thickening of the intima and the media and early plaque formation begin. Once the progressive plaque build-up reaches about 40% of the arterial diameter, narrowing of the arterial lumen begins. At this point, the late phase of atherosclerosis begins, and the obstructive vascular changes result in symptomatic vascular disease (see Fig. 2). Since penile erection is largely a vascular process, vasculogenic ED results from early changes to the endothelium-mediated smooth muscle relaxation and/or from the late occlusion of the cavernosal arteries (Montorsi et al., 2009).

Fig. 2 Summary of processes resulting in ED.

ED is frequent in patients with coronary vascular disease (CVD) with prevalence ranging between 47% and 75%. The two conditions share the same risk factors leading to atherosclerosis, to include hypertension, elevated serum lipid levels, fatty diet, obesity, physical inactivity and smoking. The ED rate is 22% in patients with acute coronary syndrome (ACS) and one vessel disease, increases to 55% in patients with ACS and multi-vessel disease, and it further rises to 65% in those with chronic coronary syndrome (Vlachopoulos et al., 2013). Some patients, however, report ED before diagnosis of CVD. Prospective studies demonstrate that about 19% of men with ED suffer from subclinical CVD and in those patients ED precedes CVD by an average of 2–3 years. Currently, this phenomenon is best explained by the “artery size” hypothesis, in which the smaller penile arteries suffer obstruction earlier than the larger coronary arteries (Montorsi et al., 2005, 2006). Alternative explanations may include differences in metabolic mechanisms as well as increased permeability of endothelial cell–cell junctions in cavernosal tissue, resulting in further insufficiency (Musicki et al., 2015).

Hypertension

Hypertension is considered one of the most hazardous cardiovascular risk factors, and it is a frequent comorbidity of men with ED (Burchardt et al., 2000). ED is found in about 68% of hypertensive men between 34 and 75 years of age. Its severity among hypertensive subjects is associated with age, duration of hypertension, and presence of peripheral vascular disease. Long-standing hypertension has been shown to increase oxidative stress and endothelial cell injury. The resulting endothelial dysfunction and impaired vasodilation of the cavernosal vasculature are the hallmarks of the initial atherosclerotic process.

Medical therapy for hypertension is quite often blamed for erectile problems, especially when there is a temporal coincidence of starting symptoms and initiation of antihypertensive drugs. Recent systematic analysis of trials evaluating erectile function concluded that only thiazide diuretics and beta-blockers may influence erectile function. ACE inhibitors, angiotensin receptor blockers, and calcium channel antagonists were reported to have no relevant or even a positive effect on erectile function (Grimm et al., 1997). Favorable effects on NO synthase and oxidative stress have been shown with Nebivolol (Bystolic®, Allergan, Parsippany, NJ) pointing out a mechanism for improvement of erectile function. Experimental studies have demonstrated an enhancement of endothelial function in aorta and corpus cavernosum with a significant reduction in penile oxidative stress and collagen content, protected cavernosal tissue against structural changes, and increased expression of endothelial NO synthase (Baumhake et al., 2008).

Dyslipidemia

Both lipid disorders and ED are common problems in older men (Seftel et al., 2004). The association between hyperlipidemia and ED is originally attributed to atherosclerosis and resulting insufficiency in penile arterial inflow. More recently, the importance of cavernosal relaxation in the erectile process has been shown, and impairment of endothelium-dependent relaxation in men with hypercholesterolemia has been firmly established.

Dyslipidemia may contribute to ED by affecting endothelial and smooth muscle cells of the penis. Oxidized low-density lipoprotein is a causative factor for the impaired relaxation response of the corpus cavernosum. Elevated serum cholesterol and reduced high-density lipoprotein (HDL) cholesterol levels are associated with an increased risk of ED.

Epidemiological studies have found that the decrease in HDL and elevation of total cholesterol are correlated with ED. Studies have also shown that arterial stenosis and occlusion caused by hyperlipidemia may be attributed to the advanced-stage mechanism of ED induced by hyperlipidemia. Dyslipidemia may damage a man's erectile function at an early stage by affecting the endothelial cells and smooth muscles of the penis and the peripheral nerves responsible for penile erection (Gandaglia et al., 2014).

Diabetes Mellitus

Approximately 35%–75% of men with type 2 DM experience erectile problems. ED occurs 5–10 years earlier in men with diabetes than in age-matched controls and increases progressively with age (Fonseca and Jawa, 2005).

ED in diabetic men has a multifactorial etiology. Hyperglycemia and increasing age result in glycation of elastic fibers and subsequent impairment of cavernosal relaxation. Advanced end-products of glycation lead to increased concentration of reactive oxidizing substances and reduced NO production thus further causing impairment in vasodilation. Diabetic neuropathy further affects normal neural transmission from the spinal cord. Duration and severity of ED correlate with glycemic control, and hemoglobin A1c has been identified as an independent predictor for ED (Romeo et al., 2000).

Hypogonadism

Testosterone plays a major role in the control of sexual function. It contributes to endothelial and smooth muscle homeostasis via reduction of pro-inflammatory markers in the vascular tissue of penile and cardiovascular systems. Low testosterone levels have pro-inflammatory and pro-apoptotic effects on endothelial cells. This chronic inflammation further impairs endothelial function, leading to a pro-thrombotic state and atherosclerotic vascular remodeling. Thus, low androgen levels are associated with reduced nocturnal, morning and sex-induced erections, reduced decreased ejaculate volume and delayed ejaculation. Low testosterone levels are also associated with an increased risk of metabolic syndrome, DM and CVD, independent of age and obesity (Allan and McLachlan, 2010; Wang et al., 2011).

Depression

Depression is a common comorbidity associated with ED and represents an affective disorder with a lifetime prevalence of 16% (Kessler et al., 2003). Its hallmark symptoms include feelings of sadness, loss of interest in pleasurable activities (to include sex), loss of appetite, sleep disturbances, fatigue, and inability to concentrate. Depressed men report primarily low libido, orgasmic dysfunction and ED. They have lower sexual desire, poorer self-image and less sexual satisfaction.

A clear link between depression and ED was established by the landmark Male Massachusetts Aging Study (MMAS), in which men who had untreated depression were almost twice as likely to report ED than their counterparts with normal mood (Araujo et al., 1998). Depression and anxiety about sexual performance can cause ED, which in turn makes performance anxiety even worse. Thus, the two conditions reinforce each other and can result in a vicious cycle. The underlying mechanism correlating them on a physiological or biochemical level has not been well established. Goldstein (2000) described a biological “triad model” to further explain this relationship and link both ED and depression to CVD. Depression is a well-established risk factor for development of CVD (Musselman et al., 1998). Mental stress results in increased release of catecholamine hormones, and those in turn impair cavernosal muscle relaxation and promote ED.

Since hypogonadism and depression share common symptoms, such as loss of libido, fatigue, dissatisfaction, and poor appetite, studies suggest that low testosterone may be a link between depression and ED.

Medical antidepressant therapy can further exacerbate existing ED. Prospective trials demonstrate that Paroxetine (Paxil®, Apotex Corp, Weston, FL) causes ED at a rate of 40%. Animal studies demonstrate that Paroxetine is an inhibitor of NO synthase and thus decreases penile production of NO and depresses erectile response of cavernosal nerves (Finkel et al., 1996; Angulo et al., 2001). Since Paroxetine has the highest rate of sexual side effects, patients discontinue it much more often than Sertraline or Citalopram (Mullins et al., 2005). When treating patients with these concomitant diseases, care should be taken in choice and proper dose adjustment of the antidepressant. Furthermore, early use of phosphodiesterase type 5 inhibitor (PDE-5i) therapy is very effective in these men and can even improve mild depression symptoms.

Modifiable Risk Factors

Diabetes Mellitus and the Metabolic Syndrome

Reaven postulated that insulin resistance and its compensatory hyperinsulinemia predisposed patients to hypertension, hyperlipidemia, and glucose intolerance and thus were the underlying causes of CVD. This unique pathophysiological condition, called the “metabolic” or “insulin resistance” syndrome, is now well defined and recognized by the World Health Organization (WHO) and the Third Report of the National Cholesterol Education Program’s Adult Treatment Panel (ATP III) (Reaven, 1988).

Currently, no direct pharmacologic therapy for treatment of the metabolic syndrome is available. Lifestyle changes, including dietary adjustments and exercise leading to weight loss, are the cornerstones of therapy. Lifestyle change has been shown to not only prevent DM, but also to improve endothelial function and decrease markers of inflammation.

Drugs shown to improve endothelial function in patients with DM include insulin and insulin sensitizers, HMG—CoA reductase inhibitors, folic acid, ACE inhibitors, Niaspan, L-arginine, and PDE-5 inhibitors.

Animal models of hypercholesterolemia demonstrate that derangements in both endothelium- and neurogenic-dependent cavernosal relaxation are reversible once total plasma cholesterol levels are normalized through dietary changes. Treating dyslipidemia medically can also have a beneficial effect on ED. PDE-5i’s are now considered to be first line treatment for ED, and there is evidence that statins improve responses to these drugs.

Obesity and Sedentary Lifestyle

A BMI of 28 kg/m² or higher and sedentary lifestyle are strong predictors of ED, and obesity is a significant independent predictor of increasingly severe ED. Although obesity was not included in Reaven’s primary list of disorders caused by insulin resistance, he acknowledged that it, too, was correlated with insulin resistance or hyperinsulinemia, and that the obvious “treatment” for what he termed “syndrome X” was weight maintenance (or weight loss) and physical activity.

Physical activity is significantly inversely associated with ED. In the Health Professionals Followup Study, men who ran for nearly 90 min/week or did rigorous outdoor activity for 180 min/week had a 30% reduced risk of developing ED. The study further demonstrated that irrespective of exercise intensity, being overweight or obese increased the risk of ED (Bacon et al., 2006).

Esposito et al. demonstrated that a diet rich in fruits, vegetables, olive oil, whole grain, legumes, and walnuts was associated with improvement in erectile function in patients with the metabolic syndrome (Esposito et al., 2004, 2006).

In summary, regular long-term physical training and interval training as well as the consumption of Mediterranean diet yield improvement in endothelial function and further reduction in markers of inflammation, thus improving erectile function.

Smoking

Cigarette smoking is a known risk factor for ED and increases the likelihood of moderate or complete ED twofold. Clinical and basic science studies provide strong evidence that smoking affects penile erection by impairing endothelium-dependent smooth muscle

relaxation and increasing overall oxidative stress damage. Smoking exposure also results in impairment of penile arterial flow and may result in an acute vasospasm of the penile arteries. The association of ED with risk factors such as CVD and hypertension appears to be amplified by cigarette smoking. Studies suggest a dose–response association between smoking and ED with a statistically significant effect observed with ≥ 20 pack-years of exposure. Non-smokers, exposed to long-term second-hand smoke, are at moderate risk of developing ED. In middle-aged men, long-term vascular effects of smoking may persist even after smoking cessation. Thus, smoking cessation in young adulthood may be needed to reduce the risk of ED (Derby et al., 2000; Feldman et al., 2000; Verze et al., 2015).

Alcohol Use

Chronic excessive alcohol intake may have an irreversible adverse effect on erectile function, as it has been demonstrated to damage the neurogenic reflex arc involved in the erectile process. Change in drinking habits or even many years of complete sobriety are not associated with erectile function improvement. This lack of conclusive data may be also related to under-reporting, as men with high alcohol intake are very unlikely to participate in any risk reduction studies (Kostis et al., 2005).

Conclusion

ED is prevalent among men and its presence is often an indicator of systemic disease. The literature indicates that each patient developing ED should be considered a cardiac patient until proven otherwise. Endothelial dysfunction is the key feature in the early phase of ED, and evidence is accumulating in favor of ED as an independent predictor of future cardiovascular events. Cardiologic assessment and aggressive treatment of underlying risk factors to ameliorate the disease process should be offered to every patient complaining of ED. Addressing modifiable risk factors frequently improves a patient's overall health and increases lifespan. The literature suggests that smoking cessation, treatment of dyslipidemia, weight loss, making healthier food choices, and increased physical activity will improve erectile function in many patients. A man's doctor can help him make such changes by referring him to a smoking cessation program, a nutritionist, a fitness expert, or any other appropriate specialist, if necessary.

Glossary

Androgen steroid hormones responsible for male sexual sex characteristics and other bodily functioning.

Apoptosis controlled and regulated cell death, a naturally occurring event.

Azoospermia complete lack of sperm in two separate semen samples.

Dysmorphic atypically formed.

Gonadotropin hormones secreted by the pituitary which stimulate the gonads, notable luteinizing hormone and follicle-stimulating hormone.

Hypogonadism reduction or absence of hormone or physiological activity related to the gonads.

Hypogonadotropic hypogonadism hypogonadism related to impaired secretion or function of gonadotropins.

Spermatogenesis the production and development of mature spermatozoa.

Oligospermia sperm concentration which is lower than normal in semen sample.

Normal Androgen Effects on Human Male Fertility

Testosterone plays a key role in the fertility of the adult male. In order for sperm to develop, intratesticular testosterone (ITT) (levels of testosterone specifically in the testes) has to concentrate to levels much higher than found in circulation. Lack of ITT can cause oligospermia or even lead to a complete loss of sperm in the semen (azoospermia) (Coviello et al., 2004). Circulating testosterone levels are commonly checked for patients to evaluate for hypogonadism, but this number can be artificially inflated from exogenous sources, and may not reflect adequate ITT levels necessary for spermatogenesis (Mulhall and Hsiao, 2014).

The hypothalamic-pituitary-gonadal (HPG) axis is a system where hormone production in the testes of males (e.g. testosterone) is controlled by a tightly regulated system initiated in the brain (see Fig. 1). This is covered in more detail in other chapters, but in brief: Gonadotropin releasing hormone (GnRH) is secreted episodically from the hypothalamus and travels via the hypophyseal portal system to the anterior pituitary. There, gonadotropic cells are stimulated to episodically release luteinizing hormone (LH)

Fig. 1 Hypothalamic pituitary gonadal axis. Taken from Roth et al., 2008.

and follicle stimulating hormone (FSH). These hormones are released into the blood stream and have specific effects on testes cells. FSH acts on sertoli cells in the testicles to produce androgen binding protein (ABP), and stimulates production of sperm. The importance of sertoli cells on spermatogenesis is multifactorial: they have a central role in maintaining the blood-testis barrier, and supply nutrients to the growing immature spermatocytes. LH acts on the interstitial leydig cells of the testis to stimulate testosterone secretion. This testosterone is partially sequestered by ABP in the sertoli cells, with resulting important effects on spermatogenesis. The remaining testosterone is released into the blood stream. Systemic circulating testosterone has effects on multiple physiological and psychological factors, notably on muscle mass, bone health, sexual functioning and overall energy levels. Testosterone can be converted to estrogen via aromatase in peripheral tissues. It can also be converted to 5-alpha dihydrotestosterone (DHT) a potent androgen via 5-alpha reductase, which can also act on the androgen receptor.

Testosterone which becomes bound to ABP in the testicle acts on intracellular androgen receptors found in sertoli cells with resulting DNA activation and transcription of several proteins which promote spermatogenesis, and prevent spermatocyte apoptosis or cell death. Testosterone is actively sequestered in the seminiferous tubules and can have a concentration 25–100 times higher than in the blood circulation. The exact concentration of ITT required for spermatogenesis has not been defined, however, studies have shown that intratesticular levels similar to serum levels are not sufficient.

Acting as negative feedback, testosterone circulates back to both the hypothalamus and the anterior pituitary and directly inhibit further release of GnRH, FSH and LH. Estrogen also acts to inhibit the hypothalamus, and possibly the anterior pituitary (Roth et al., 2008). The stimulation of sertoli cells by FSH also causes secretion of inhibin B which acts on the anterior pituitary, inhibiting release of FSH. Thus, a balanced homeostasis occurs in the adult male for production of testosterone (Fronczak et al., 2012).

Exogenous Androgens and Their Effects on Male Fertility

Men who have low circulating testosterone levels (hypogonadism) are commonly treated with exogenous androgens to improve the systemic effects of testosterone, such as muscle mass, bone health, sexual functioning and energy levels. The prevalence of hypogonadism in the age group 20–45 has been estimated at 3–8% (Behre et al., 2016). However, the number of men being diagnosed with hypogonadism is increasing, with a four fold increase in men diagnosed and subsequently treated with exogenous testosterone in the age group 18–45 between 2003 and 2013 (Dohle et al., 2003). Returning the circulating testosterone levels to normal exogenously can have benefits on mood, muscle mass, and energy, however, it has a direct inhibitory effect on LH and FSH production via the normal feedback loop. The reduction in LH prevents the production of testosterone from leydig cells, and the reduction in FSH prevents the formation of ABP. The end result being that intratesticular levels of testosterone falls drastically. This reduction in ITT prevents spermatogenesis from occurring. Thus, patients treated with exogenous hormone therapy may have the benefits of systemic hormones, but have the unwanted or unexpected side effect of infertility. Unfortunately, many practitioners including urologists are unaware of this serious effect. Similarly, many young men use exogenous androgens to use as an exercise supplement, reportedly 1–6% of high school seniors (Depenbusch et al., 2002, Shaw et al., 2010).

Interest in the use of exogenous testosterone to inhibit spermatogenesis prompted its evaluation as a contraceptive agent in two landmark trials by the WHO in 1990 and 1996. Intramuscular testosterone was given to men weekly, with a 98% efficacy of reducing sperm to at least oligospermic levels temporarily, and 77% had a continued azoospermia while on the testosterone supplements (WHO, 1990, 1996). A more recent study involving 320 men were treated with norethisterone enanthate (form of progesterone) and testosterone IM injections every 8 weeks had a 95.9% efficacy rate at reducing sperm levels to < 1 million/mL within 24 weeks, and upon cessation of treatment there was a 94.8% reversibility of suppression within 1 year (Behre et al., 2016).

In patients who desire future fertility, studies show that in most patients, withdrawing the hormone therapy can increase circulating LH/FSH and subsequently return spermatogenesis. This takes a variable length of time, between 3 months and 2 years. However, these patients will lose the benefit of normalized systemic androgen levels, unless another method to stimulate hormone production is used.

Exogenous Products Affecting Androgen Production and Fertility

Synthetic testosterone (gel, cream, transdermal patch, buccal tablets, intramuscular injections, subdermal implants): commonly prescribed to male patients who are symptomatic and hypogonadal and not interested in future fertility. Synthetic testosterone acts in the same way as endogenous testosterone, and has feedback inhibition on the HPG axis, can be converted to DHT and estrogen as above. Levels are consistently monitored by physicians. Care must be made with any topical application to apply it to areas which would not normally be contacted by people in whom increased androgens could be dangerous, namely children and women. Otherwise premature virilization may occur.

Anabolic androgenic steroids (AAS): the benefit of exogenous steroid hormones on muscle mass and energy levels has been known since the early 1900s, and it was quickly adopted into use as a performance enhancing drug in athletes. Use in amateur male athletes is increasing, with an estimated 3.0% to 4.2% lifetime prevalence (Ramasamy et al., 2015). Unfortunately, AAS is associated with multiple medical issues including: testicular atrophy, low endogenous testosterone production, sexual dysfunction, gynecomastia (enlarged painful breast development), liver dysfunction, alopecia (hair loss), high blood pressure, dyslipidemia. Similar to exogenous synthetic testosterone therapy, AAS inhibits release of GnRH and LH/FSH and can cause oligo- or azoospermia. Users frequently get AAS over the internet, and so are not made aware of side effects or risks of their use. Men

identified as using AAS must be carefully counseled as to these risks, and specialized care via an andrologist or endocrinologist should be sought.

Selective Estrogen Receptor Modulators (SERMs): exogenous medications which act as competitive antagonists at the estrogen receptor. By blocking the negative inhibitory effect of estrogen (formed by aromatization of testosterone) on the hypothalamus, and perhaps the anterior pituitary, SERMs increase the circulating levels of LH and FSH with subsequent increases in testosterone levels. Data on improvement in semen quality is mixed. Tamoxifen and clomiphene citrate are the most commonly used medications in this class, and are FDA approved for breast cancer therapy and in female fertility, respectively. It is used off label in men. Multiple small prospective studies have showed a daily or every other day dose schedule of clomiphene citrate in hypogonadal men can be effective, and cost effective (Rao et al., 2017), in increasing circulating testosterone to desired levels (Shabsigh et al., 2005, Shabsigh et al., 2005). A 3 year follow up showed that patients had no adverse effects and had sustained improved levels (Katz et al., 2012).

Aromatase inhibitors: aromatase is a CYP450 enzyme found in liver, testes, brain and adipose tissue and catalyzes the synthesis of estrogen from testosterone. Inhibitors of aromatase, including anastrozole and letrozole have classically been used in breast cancer therapy to limit estrogen formation. Their use in men is not FDA approved, but has been used to prevent estrogenic feedback on the HPG axis and limit the side effects of increased estrogen, notably gynecomastia (Shabsigh et al., 2005). Side effects of their use include concern for worsening bone health. Some studies have shown an increased risk of clotting disorders including pulmonary embolism and stroke (Lycette et al., 2006).

Human chorionic gonadotropin (hCG): An endogenous protein made in men and women, it is comprised of an alpha and beta subunit. The alpha unit is identical to the alpha unit of both LH and FSH, and the beta unit is identical to the LH beta unit excepting 24 additional amino acids. hCG can stimulate the LH receptor and have downstream upregulation of testosterone production, increasing both circulating testosterone and IIT. This makes it a useful therapy in treating patients who have hypogonadotropic hypogonadism, as they in theory should have normally functioning testicular tissue, though may have atrophied from prolonged gonadotropin deficiency (Shabsigh et al., 2005). It is not FDA approved for hypogonadism of aging or hypergonadotropic hypogonadism. A retrospective review of 26 hypogonadal men treated with exogenous testosterone and low dose hCG intramuscular doses every other day showed sustained increased circulating testosterone levels and they all maintained their semen parameters (Shabsigh 2005). A small prospective study on men with hypogonadism treated with hCG and human menopausal gonadotropin (hMG) were able to induce spermatogenesis, maintain testosterone levels, and maintain sperm production over a 2 year period of followup (Depenbusch 2002). Hsieh et al. showed that a combination of testosterone and intermittent hCG can also maintain spermatogenesis (Hsieh 2013).

Medications With Male Reproductive Side Effects

Mary K Samplaski, University of Southern California, Los Angeles, CA, United States

Ajay K Nangia, University of Kansas Medical Center, Kansas City, KS, United States

© 2018 Elsevier Inc. All rights reserved.

Background

- Men of reproductive age commonly take medications.
- Testing on the reproductive effects of these medications is not standardized.
- Testing for all possible facets of reproductive impairment is challenging:
 - Alterations of the hypothalamic-pituitary-gonadal (HPG) axis
 - Effects on sperm production or function
 - Impaired sexual function

Anti-Inflammatories

- > 30 NSAID pills/month may result in lower sperm concentration and motility, and a higher percentage of dead sperm.
- Limited human data
- Animal data seems to suggest that occasional use is not harmful

Testosterone

- Exogenous testosterone will decrease sperm counts and should not be used in men trying to achieve a pregnancy.
- Anabolic steroid users often have supra-physiologic serum testosterone concentrations, which may further suppress sperm production.

Phosphodiesterase Inhibitors

- Studies on their relationship with sperm function have yielded varying results
- Sub-fertile men may have a more pronounced (and negative) response

Psychotropic Medications

- Known to affect sexual function: libido, erectile and ejaculatory function.
- Limited data on semen parameters and sperm function.
- SSRI and lithium use may result in a reduced sperm concentration, motility and morphology.
- SSRI use is correlated with an increase in sperm DNA fragmentation index.

Anti-Hypertensive Agents

- Most cause some degree of vasculogenic sexual dysfunction, which can indirectly impair fertility
- Germinal (testicular) angiotensin-converting enzyme (ACE) is found exclusively in post-meiotic male germinal cells, and its presence is correlated with sperm concentration and motility, sperm function and fertilization. However, men taking angiotensin-converting enzyme inhibitors (ACE-Is) do not seem to have altered semen parameters or fertilizing ability.

Antibiotics

- Limited data and the co-existing inflammation may also impact fertility
- There is data to suggest that aminoglycosides and ciprofloxacin may negatively impact semen parameters.

5 α -Reductase Inhibitors

- In healthy men, these medications will result in ~30% decrease total sperm counts.
- Some men have a heightened sensitivity and will have a more pronounced response.
- Some men may develop “Post Finasteride Syndrome.”

Alpha-Blockers

- Most will result in some degree of ejaculatory dysfunction, ranging from retrograde ejaculation to decreased ejaculatory volume or impaired force of seminal emission.
- May also alter libido and erectile function.

Chemotherapeutic Agents

- Multi-agent chemotherapeutic regimens will minimize single agent toxicity.
- High gonadotoxic risk: alkylating agents (cyclophosphamide, chlorambucil, mustine, ifosfamide), nitrogen mustard derivatives (busulfan, melphalan), chlormethine, procarbazine, dacarbazine, chlormethine, and the MOPP regimen (nitrogen-mustard, oncovin (vincristine), procarbazine, and prednisone).

- Biologic or targeted therapies may also have effects on male fertility, although limited data.

Transplant Medications

- Limited and conflicting human and animal data.

Background

Sixty-eight percent of men ages 18–44 years have used medications (prescription or over the counter), increasing to 81% in men 45–64 years of age. In addition, the quantity of medications used increases with age (Kaufman et al., 2002). Both these medications themselves and the underlying disease states may impair reproductive ability. Testing on the reproductive effects of these medications is not standardized and few human studies have been performed. In addition, testing for all possible facets of reproductive impairment is challenging, including through alterations of the hypothalamic-pituitary-gonadal (HPG) axis, effects on sperm production or function, or impaired sexual function.

Anti-Inflammatories

While anti-inflammatories are among the most commonly used medications, their effects in humans remain poorly studied. In theory, a relationship could be present as cyclooxygenase (COX) enzyme inhibitors play an important role in the regulation of reproductive functions in females. A 2003 study on nonsteroidal anti-inflammatory drugs (NSAID) from 1376 men found a non-significant 16% decrease in sperm concentration in men who reported consuming > 30 NSAID pills/month. Linear regression analysis found a correlation between NSAID doses and the percentage of dead cells, sperm motility and morphology (Martini et al., 2003).

Acetaminophen, or paracetamol, bears some structural similarities to estradiol and progesterone, and therefore has been investigated as a sex steroid modulator (Anderson et al., 1998; Cramer et al., 1998). There are no human studies on this medication. In the largest animal study, male rats were treated with paracetamol at 500 or 1000 mg/kg (maximum dosing in humans 15 mg/kg) for 30 days, and libido, ejaculatory ability and fertility were assessed (Ratnasooriya and Jayakody, 2000). After 30 days, there was a decline in libido, sexual vigor and sexual performance. Mating studies found a decrease in pregnancies, fertility index, implantation index and number of implants. These effects were thought to be due to reduced sperm counts, motility and a reduced sperm fertilizing potential. Histologically, treated rats had an apoptosis of spermatocytes and spermatids, and reduction in testicular weight. The effect of paracetamol on sperm fertilizing ability and miscarriages, was thought to be due to its lipid peroxidation effects, which may impact sperm capacitation ability (Wendel et al., 1979). All these effects were reversible (Ratnasooriya and Jayakody, 2000).

There have been several other smaller animal studies on acetaminophen/paracetamol. A study of 6 rats that were treated with a single dose of paracetamol found altered seminiferous tubules, Sertoli cells and spermatids after treatment (Yano and Dolder, 2002). Furthermore, treatment with medications to mitigate oxidative stress may negate paracetamol-induced reproductive damage (Aksu et al., 2016). Finally, male mice treated with oral acetaminophen had an increase in sperm abnormal morphology and a decrease in offspring pup weights (7% in controls vs. 16% in the high-dose group) (1997).

There have been similarly no studies of ibuprofen on semen parameters in humans. Mouse studies have shown that after treatment with low and high doses of ibuprofen, for 35, 70 and 105 days, all of the treated mice had an increase in spermatozoa with immature chromatin, and there was a decline in sperm concentration, motility and normal forms (Roodbari et al., 2015). Conversely, in mice exposed to hypoxic conditions, ibuprofen was actually protective against teratozoospermia and elevated sperm DNA fragmentation (Vargas et al., 2011).

Aspirin, or acetylsalicylic acid, has been investigated. In the only human study, healthy adult males who used moderate amounts of aspirin (> 500 mg/wk) had a moderate decrease in sperm motility (62% vs. 44%) (Stutz et al., 2004). A study looking at rats given aspirin at 12.5 mg/kg for 30 and 60 days found that treated animals had reduced sperm density, count and motility in the cauda epididymis and testis, and histologic evaluation found a reduced number of primary spermatogonial cells (Vyas et al., 2016). There are no animal studies on the effects of aspirin on male semen parameters or reproductive organs, but there are studies demonstrating its protective effect (Karaguzel et al., 2012), and as such, occasional use is likely not detrimental.

There is only a single study looking at the male reproductive toxicity effects of naprosyn. After treatment with naprosyn for 35 days, male rats had a reduction in sperm count (600×10^6 vs. 375×10^6) and motility (95% vs. 35%), and induced damage of seminiferous tubules without effecting plasma hormone levels (Uzun et al., 2015).

Exogenous Testosterone

Exogenous testosterone suppresses the HPG axis, which results in a profound suppression in spermatogenesis (Gonzalo et al., 2002), an effect which is more pronounced with intramuscular (vs. transdermal) formulations (Ko et al., 2012). The largest and

longest study looking at this found that after intramuscular testosterone replacement therapy for 30 months, 95% of men became azoospermic or severe oligospermic with a sperm concentration of < 1 million. It is reassuring that all but 2 men recovered spermatogenesis, with a median recovery time to baseline sperm production of 182 days. Conversely, it is concerning that 2 men did not recover spermatogenesis (Liu et al., 2006). These findings have been corroborated by other studies (Rahnema et al., 2014; Kim et al., 2013). Because of this, exogenous testosterone should not be used in men of reproductive age.

Although “exogenous testosterone” is often medically prescribed, the most commonly abused illicit anabolic steroids are types of exogenous testosterone. In this population, the serum testosterone concentrations are typically supra-physiologic, which may further suppress sperm production. Animal models have demonstrated that after anabolic steroid discontinuation, Leydig cells tend to proliferate but remain below regular counts, even after prolonged periods, suggesting a delay in recovery of testicular function after anabolic steroid use (Nagata et al., 1999). Likewise, even when hCG is used as an adjunct to anabolic steroids use, lower motility and poorer morphology is seen, even after anabolic steroids are discontinued (Karila et al., 2004).

Phosphodiesterase Inhibitors

Several PDE isoforms have been found in human sperm (Sinclair et al., 2000), and both sildenafil and vardenafil have been found in the ejaculate after oral administration (du Plessis et al., 2004). Studies on their relationship with sperm function have yielded varying results. In vitro studies have shown conflicting results regarding the effect of sildenafil on human sperm motility (du Plessis et al., 2004; Purvis et al., 2002; Aversa et al., 2000; Jannini et al., 2004), capacitation and the acrosome reaction (Lefievre et al., 2000; Burger et al., 2000). In vivo studies have shown that, asthenozoospermic and normozoospermic men treated with oral sildenafil had no difference in semen parameters or acrosome reaction rate (Yang et al., 2014). Similarly, a double-blinded, placebo controlled study of 200 men treated daily with daily sildenafil, vardenafil or placebo for 6 months, did not show any alterations in semen parameters or reproductive hormones (Jarvi et al., 2008).

Data for tadalafil are similarly heterogeneous. A human study of fertile men treated with tadalafil versus placebo showed no difference in semen or reproductive hormones (Hellstrom et al., 2003). However, in a small study of subfertile men, sildenafil resulted in an increase in sperm progressive motility (37.0% vs. 28.5%), but tadalafil resulted in a decrease in motility (21.5% vs. 28.5%) (Pomara et al., 2007). Finally, a recent study of fertility unaware men treated with tadalafil 5 mg daily for 12 weeks found that treated men actually had an increase in sperm counts and motility, making the daily use of tadalafil for benign prostatic hyper trophy reassuring (Corvasce et al., 2015). Due to small numbers of patients, these data are difficult to extrapolate from, but may indicate a differential response to tadalafil versus sildenafil, and that subfertile men may have a more pronounced response to these medications.

Psychotropic Medications

Psychotropic medications are known to affect sexual function especially libido, erectile and ejaculatory function. These agents may also affect the HPG axis at many levels, resulting in lower FSH and LH levels, hyperprolactinemia and hypogonadism, and other abnormalities (Hendrick et al., 2000). Limited data has shown a reduction in semen volume and sperm motility (Levin et al., 1981) after treatment with tricyclic antidepressants in vivo, and in vitro (Maier and Koinig, 1994). Phenothiazines, monoamine oxidase inhibitors and lithium can result in sexual performance issues (Serretti and Chiesa, 2011).

Selective serotonin reuptake inhibitors (SSRIs) are often used to treat premature ejaculation or performance-anxiety related ED. Their effects on male fertility are unclear. Long-term use may result in a 50–60% incidence of ED, delayed or absent ejaculation (Montejo et al., 2001). For studied medications, the order of this effect is: paroxetine $>$ fluoxetine $>$ sertraline (Montejo et al., 2001). SSRIs have also been shown to be spermicidal in vitro, likely from oxidative phosphorylation (Kumar et al., 2006). Three prospective cohort studies conducted in men exposed to SSRIs found altered semen parameters after as little as 3 months of exposure, including reduced sperm concentration, motility and morphology (2015). A rat study using fluvoxamine demonstrated resulted apoptosis in testicular tissue (Galal et al., 2016). Similarly, rats treated with dapoxetine had a dose-dependent decrease in sperm motility and normal forms, and an increase in fetal resorptions (ElMazoudy et al., 2015). SSRI use has also been associated with increased sperm DNA fragmentation (30.3% vs. 13.8% (Tanrikut et al., 2010)) and decreased sperm motility, independent of type of SSRI, but related to treatment duration (Safarinejad, 2008).

Rat models have identified a dose-dependent reduction in sperm concentration, motility, morphology and fecundity after treatment with lithium (Toghyani et al., 2013; Thakur et al., 2003), and histologically a loss of germ cell attachment (Zarnescu and Zamfirescu, 2006). Human studies on sperm and lithium are scant and show only an in vitro reduction in sperm viability (Levin et al., 1981).

Antihypertensive Medications

Most antihypertensive agents cause some degree of vasculogenic sexual dysfunction, which can indirectly impair fertility (Ko et al., 2002). In mice, β -blockers have been shown to result in reversible impaired sperm concentration, motility and morphology

(el-Sayed et al., 1998; Nusier et al., 2007). A recent study of rats treated with cisplatin +/- concurrent carvedilol found that carvedilol mitigated cisplatin-induced testicular and spermatogenic injury by reducing inflammatory burden, enhancement of steroidogenesis and spermatogenesis, and mitigation of testicular histopathological damage (Eid et al., 2016). Human studies are limited and conflicting. In vitro studies have found that propranolol may inhibit human sperm motility (White et al., 1995), however, in vivo studies have found no change in semen parameters (Mahajan et al., 1984).

Spironolactone reduces testosterone production, increases the conversion of testosterone to estrogen and impairs DHT receptor binding. In humans, it has been shown to cause gynecomastia and decrease sperm concentration and motility (Caminos-Torres et al., 1977).

While the calcium ion is involved in in vitro sperm motility, capacitation and the acrosome reaction (Morakinyo et al., 2011), the clinical effect of calcium channel blockers on semen parameters and sperm function is not as clear. In vivo murine studies of calcium channel blockers have found impaired in semen parameters, the acrosome reaction and zona penetration (Saha et al., 2000a), and decreased litter size (Morakinyo et al., 2011). Human in vitro incubation studies with diltiazem have shown that at higher doses there is a decline in sperm motility (Aaberg et al., 1989). In addition, a contraception study looking at vasal irrigation with diltiazem at the time of vasectomy resulted in a reduction in sperm motility, viability and cervical mucus penetration (Wood et al., 2003). However, in humans, no change in fertilization rate in in vitro fertilization (IVF) or non-IVF cycles was seen in men using calcium channel blockers (Katsoff and Check, 1997).

There have been no human studies on semen parameters in men treated with angiotensin-converting enzyme inhibitors (ACE-I) or angiotensin receptor blockers, although animal studies suggest that they may play a role. Rat studies have found conflicting results on the impact of treatment with ACE-I on semen parameters (Okeahialam et al., 2006; Saha et al., 2000b). A single in vitro human sperm incubation study found a decrease in motility (Shibahara et al., 2001). From a physiologic perspective, angiotensin II has been found to localize to human sperm, and levels are correlated with sperm motility (Gianzo et al., 2016). In addition, the germinal (testicular) ACE is found exclusively in post-meiotic male germinal cells (Li et al., 2014). Its presence is correlated with sperm concentration and motility (Shibahara et al., 2001), as well as multiple other sperm functions (Zalata et al., 2012), and this enzyme is crucial for fertilization (Kondoh et al., 2005).

Antibiotics

Interpretation of the effect of antibiotics on male fertility can be challenging, as the co-existing inflammation may negatively impact male fertility. In addition, recent data are not available for most of these medications.

A 1998 in vitro study used sperm from normospermic men cultured with increasing concentrations of several antibiotics, with variable negative effects on vitality and motility (Hargreaves et al., 1998). There have been no human studies on the effects of penicillins and cephalosporins on human sperm, but in vitro animal studies suggest a decline in sperm production and motility (Timmermans, 1974; Antohi et al., 2011). Limited studies of effects of trimethoprim-sulfamethoxazole (TMP-SMX) generally show minimal effects on human sperm (Murdia et al., 1978; Merino and Carranza-Lira, 1995). In the only human study looking at this drug, erythromycin for the treatment of men with asthenospermia resulted in no change in semen parameters (Baker et al., 1984). Similarly, therapeutic doses of nitrofurantoin have not been shown to affect semen parameters (Albert et al., 1975).

Ciprofloxacin for the treatment of positive human male semen cultures has not been shown to adversely affect sperm (Merino and Carranza-Lira, 1995). However, in a 2015 review, total motile sperm count, testis weight and reproductive histology was decreased after treatment with ofloxacin (Khaki, 2015).

Doxycycline has been studied in infertile men with low-level leukocytospermia. In this population, treatment resulted in an increase in natural pregnancy rates (47% vs 20%) (Hamada et al., 2011).

Aminoglycosides, including neomycin and gentamicin, have been shown to negatively impact semen parameters. A remote article found that the administration of gentamicin prior to prostate surgery resulted in the cessation of meiosis at the primary spermatocyte level and in increase in abnormal forms (Timmermans, 1974). Likewise, the use of neomycin to treat urologic inflammatory conditions has demonstrated a negative impact on sperm count, concentration and motility (Schlegel et al., 1991). Rat studies have confirmed that gentamicin results in a decrease in sperm count, motility and viability (Khaki et al., 2008).

Sparse data exist for the antifungals, but the available data does show a decline in testicular function. Ketoconazole has been shown to result in an increase in serum LH and a decrease in serum testosterone (Irsy et al., 1991). It has also been shown to result in impaired sperm motility when administered orally to dogs and monkeys (Vickery et al., 1985). This is the only antifungal for which there is any data.

5 α -Reductase Inhibitors

The available literature shows that most (but not all) men will not experience negative reproductive effects after treatment with 5 α -reductase inhibitors (5ARIs). At full doses, both dutasteride (0.5 mg/day) and finasteride (5 mg/day) result in a reversible ~30% decrease total sperm counts (Amory et al., 2007). Similarly, finasteride (1 mg/day) has not been shown to alter semen parameters in fertile men (Overstreet et al., 1999). However, in both studies, a subgroup of approximately 5% of men demonstrated a heightened sensitivity, with decreases in total sperm count to <10% of baseline values (Overstreet et al., 1999; Amory et al.,

2007). Accordingly, in men presenting for fertility evaluation who had been treated with finasteride 1 mg daily, a mean 11.6-fold increase in sperm concentration was seen after finasteride discontinuation (Samplaski et al., 2013). Finally, a single case report has identified an increase in sperm DNA fragmentation rate with finasteride (Tu and Zini, 2011).

Men taking 5ARIs may also be at risk for “Post Finasteride Syndrome”, a constellation of sexual dysfunction, ED, diminished sexual desire and ejaculatory dysfunction (Gur et al., 2013; Traish et al., 2011; Irwig and Kolukula, 2011). In two 1-year studies, men taking finasteride 1 mg daily had more sexual adverse events than placebo (4.2 vs. 2.2%); decreased sexual desire (1.9 vs. 1.3%), ejaculatory dysfunction (1.2 vs. 0.7%) and ED (1.4 vs. 0.9%) (Kaufman et al., 1998; McClellan and Markham, 1999). Similar results have been reported for finasteride 5 mg daily (Wessells et al., 2003; Byrnes et al., 1995) (Nickel et al., 1996). Alarming, in some men the sexual dysfunction persists even after discontinuation of the 5ARI. After finasteride discontinuation, 20% of men reported persistent adverse sexual effects for > 6 years (Mondaini et al., 2007). Dutasteride has been shown to have a similar adverse sexual side effect profile (Clark et al., 2004; Gur et al., 2013; Debruyne et al., 2004; Roehrborn et al., 2002).

Alpha-Blockers

Alpha adrenoceptor blockers inhibit sympathetic smooth muscle innervation to the distal ureter, prostate and male reproductive tract, and may cause ejaculatory dysfunction, ranging from retrograde ejaculation to decreased ejaculatory volume or impaired force of seminal emission. Four subtypes of α_1 receptors have been described, and the variation in side effects likely relates to variable affinities for these receptors. These effects do seem to be reversible. In a randomized 3-way crossover study in normal men, >20% decrease in ejaculate volume was seen in 89.6% of men taking tamsulosin 0.8 mg, 20.8% of men taking alfuzosin and 12.5% of men taking placebo (Hellstrom and Sikka, 2006). A meta-analysis looking at sexual side effects with α -blockers, found that ejaculatory dysfunction was more common with α -blockers overall compared with placebo (OR: 5.88). Tamsulosin had an odds ratio of 8.58 ($P = 0.006$), silodosin had an odds ratio of 32.5 ($P < 0.0001$), and doxazosin and terazosin were similar to placebo (Gacci et al., 2014). For most other α -blockers, ejaculatory dysfunction is found in 0–1% to 1.5% of men (Chen et al., 2009; Kaplan, 2009).

Limited studies have looked at the effect of α -blockers on libido and erectile function. Decrease libido is found in 1–2% of men taking α -blockers, particularly with tamsulosin at the 0.8 mg dose (Roehrborn et al., 2008; Lepor et al., 2012). ED is found in 3.8% of men taking tamsulosin (Roehrborn et al., 2008). Studies on the rates of ED and altered libido in other α -blockers are lacking.

α -Blockers have also been shown to alter semen parameters in healthy men. Alfuzosin 10 mg daily resulted in an increase in sperm count of 46.2×10^6 , and tamsulosin resulted in a decrease by 54.6×10^6 . Both drugs resulted in a decline in sperm motility, 13.8% after tamsulosin and 0.4% after alfuzosin (Hellstrom and Sikka, 2009). Studies on semen parameters for other α -blockers are lacking.

Chemotherapeutic Agents

Chemotherapeutic agents may damage sperm via effects on spermatogonial stem cells, Sertoli or Leydig cells (Boekelheide, 2005). Stem cell damage may result in genetically abnormal sperm precursors, including sperm diploidy (Genesca et al., 1990; De Mas et al., 2001). While multi-agent chemotherapeutic regimens will minimize single agent toxicity, these regimens may also make it difficult to determine the toxicity of the individual agents (Meistrich, 2013).

Some of the most gonadotoxic regimens include alkylating agents (cyclophosphamide, chlorambucil, mustine, ifosfamide), nitrogen mustard derivatives (busulfan, melphalan), chlormethine, procarbazine, dacarbazine, chlormethine, and the MOPP regimen (nitrogen-mustard, oncovin (vincristine), procarbazine, and prednisone). Moderate risk chemotherapeutic agents include cisplatin, carboplatin, doxorubicin, BEP (bleomycin, etoposide, cisplatin) and ABVD (adriamycin, bleomycin, vinblastine, dacarbazine). Low risk chemotherapeutic agents include antimetabolites, topoisomerase inhibitors, vinca alkaloids (vincristine, vinblastine), methotrexate, dactinomycin, dacarbazine, mercaptopurine, and bleomycin (Pont and Albrecht, 1997; Howell and Shalet, 2001; Wallace et al., 2005).

The alkylating agent, cisplatin, is commonly used in the treatment of testicular cancer, and is considered highly gonadotoxic (Boekelheide, 2005; Fung and Vaughn, 2011). In 1191 testis cancer survivors, at 11 years follow-up, the median sperm concentration for men treated with surgery alone was $30 \times 10^6/\text{mL}$, versus $18 \times 10^6/\text{mL}$ in men treated with chemotherapy containing cisplatin $< 850 \text{ mg}/\text{m}^2$, and $1 \times 10^6/\text{mL}$ in men treated with in chemotherapy containing cisplatin $> 850 \text{ mg}/\text{m}^2$ ($p = 0.001$) (Brydoy et al., 2012). These treatments also correlated with post-treatment paternity (Brydoy et al., 2012). In some men, the only manifestation of gonadal insult seen is altered gonadotropin or testosterone levels, and up to 34% of testis cancer survivors receiving cisplatin-based chemotherapy will have lower testosterone levels than chemo-naïve patients (Brydoy et al., 2012; Huddart et al., 2005). This may secondarily affect male fertility by altering libido, erectile function and sexual satisfaction (Huddart et al., 2005; Fung and Vaughn, 2011).

Non-Hodgkin lymphoma was traditionally treated with the R-CHOP regimen (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone), which may result in long-term azoospermia (da Cunha et al., 1984). The ABVD regimen was developed because of this. A recent multicenter, prospective study looked at the effect of lymphoma treatments on sperm up to 24 months after treatment (Bujan et al., 2014). After 24 months, >90% of men were expected to recover normal sperm count after ABVD, compared with 61% for CHOP (Bujan et al., 2014). Within the CHOP regimen, the agent with the most significant gonadotoxicity

is cyclophosphamide. In general, a cumulative dose of 19 g/m² will produce prolonged azoospermia (Rivkees and Crawford, 1988), but when used as part of a regimen, lower doses may result in oligospermia (Eghbali and Papaxanthos-Roche, 2010).

Biologic or targeted therapies may also have effects on male fertility. Animal studies on imatinib, a tyrosine kinase inhibitor (TKI), have shown conflicting results, with some demonstrating normal spermatogenesis, and others demonstrating decreased litter sizes and elevated gonadotropins (Nurmio et al., 2008; Schultheis et al., 2012). A study of 13 peri-pubertal boys taking imatinib long-term for chronic myeloid leukemia found no alternations in inhibin B or serum testosterone levels after treatment (Tauer et al., 2014). Limited data suggest that spermatogenesis is maintained with imatinib, although gynecomastia may be seen in up to 20% of men and seems to be associated with Leydig cell dysfunction (which is seen with most TKIs (Meistrich, 2013)) (Gambacorti-Passerini et al., 2003). Once treatment is completed, men treated with imatinib seem to produce normal pregnancies and offspring (Ault et al., 2006). One mouse study found that both imatinib and sorafenib adversely affected sperm count and motility, in a reversible fashion (Shetty and Bairy, 2015). Sunitinib treatment in rats was found to have no effect on copulation, fertility, conception indices, sperm concentration, motility or morphology (Coburn et al., 2012).

Transplant Medications

The effect of transplant agents on the male reproductive system is extremely limited and controversial. A survey on the fertility of 164 male renal transplant recipients who underwent a long-term treatment with cyclosporine A (1.2–3 mg/kg/d), azathioprine (50–75 mg/d) and prednisone (5–10 mg/d) found that long-term treatment with small-dose immunosuppression had no obvious effect on fertility (Xu et al., 2009). Semen parameters were not investigated. A different group looked at prednisone at varying doses (5, 12.5 or 25 mg daily for one month) to determine if treatment improved seminal parameters in infertile oligozoospermic patients with signs of accessory gland inflammation on genital ultrasound. At all doses there was an increase in sperm counts (Milardi et al., 2017). Furthermore, corticosteroids have been used in the treatment of anti-sperm antibodies for many years, and do not seem to be harmful to semen parameters (Ulcova-Gallova et al., 2000).

In rats, cyclosporine and sirolimus at post renal transplant doses have been found to significantly affect testicular development, the HPG axis, and result in profound testicular histological changes under light and electron microscopic examinations (Chen et al., 2013). Reduced total sperm counts, motility, and normal morphology were also seen (Chen et al., 2013). Tacrolimus only resulted in a mild reduction in sperm counts, without histological evidence of testicular injury (Chen et al., 2013). Conversely, a different rat study found that tacrolimus induced adverse histopathological changes in the seminiferous tubules, resulting in spermatogenic damage and reduction in the number of Sertoli cells (Caneguim et al., 2009).

There have been rare human studies performed. In a single case study, a male of reproductive age was initially placed on sirolimus and oligospermia resulted. When his immunosuppression was changed to tacrolimus, spermatogenesis recovered (Skrzypek and Krause, 2007). A larger study looked at the ejaculates of 37 kidney transplant recipients treated with either: FK506 (tacrolimus), mycophenolate mofetil and prednisone; or cyclosporine, azathioprine and prednisone (Cao et al., 2006). There were no changes in viability and velocity of average path between groups (Cao et al., 2006). Sperm morphology and curve line velocity in the FK506 group were higher and lower, respectively, than those in the cyclosporine group; These data suggest that FK506 may be less gonadotoxic than cyclosporine (Cao et al., 2006).

Conclusions

For an alarming number of medications there are limited human data, which may make counseling patients difficult. While many medications may affect male fertility by altering sexual performance, those that cause alterations in semen parameters and possible adverse outcomes in the offspring are more concerning. Couples should be counseled of these limitations and risks, and the appropriate precautions taken if possible based on this very limited data.

Imaging in Male Reproductive Medicine

Introduction

Gone are the mystical days of four bodily humors, now replaced with imaging techniques that allow us to peer into every microscopic crevice of the human body. Beginning in the 1890s, Wilhelm Röntgen and others began to systematically study the emission of “invisible rays” from cathode tubes, creating the first X-ray images. Ultrasound (US) waves were sent out and received by a transducer to create medical images beginning in the 1940s, revolutionizing many specialties. The Japanese duo Takahashi and Ouchi reported the initial urologic application of US in 1963 with transrectal imaging of the prostate (Takahashi and Ouchi, 1963). By capturing the Doppler effects of US waves, clinicians were further able to place a “stethoscope” on the testicles by 1976, evaluating for blood flow problems including testicular torsion (Watanabe et al., 1974).

Imaging modalities are particularly useful in medical conditions that may be difficult to diagnose or treat such as male infertility. Fecundity involves the complex interplay of various physiologic pathways of both male and female partners. The inability to conceive after 12 months of trying (or 6 months if female age ≥ 35) is not rare, affecting nearly 15% of the reproductive-aged population. Male factors are implicated in half of couples who are struggling to conceive which emphasizes the need for all men in affected couples to undergo their own specialized evaluation.

Initial male evaluation consists of a thorough medical history including sexual/reproductive history and physical examination. Examination by a male infertility specialist is important for evaluation of testicular size, consistency, and masses in addition to abnormalities of the sperm transport system, namely the epididymis and vas deferens. Evaluation for testicular varicose veins, also known as a varicocele, should also be performed. Laboratory testing should consist of at least one semen analysis according to the American Urologic Association (AUA) guidelines on male infertility (Jarow et al., 2010). Low or absent sperm concentrations (oligospermia and azospermia, respectively) may indicate an underlying pathology such as varicocele, obstruction of the reproductive tracts, or a testicular tumor.

The lack of robust laboratory diagnostic tools other than a semen analysis creates a void that medical imaging helps to fill. Shortly after the advent of Doppler imaging, urologists began correlating male infertility with imaging results, studying the relationships between US-proven varicoceles and semen parameters. Infertility specialists currently employ a variety of imaging modalities including standard X-ray/fluoroscopy, angiography, computed tomography (CT), US, and magnetic resonance imaging (MRI). These imaging studies aid the diagnosis of the subfertile male patient male by supplementing the clinical evaluation and identifying potentially correctable etiologies. The purpose of this article is to review the current application of medical imaging modalities in male reproductive evaluation and treatment.

Imaging Modalities

X-ray

Standard X-rays and fluoroscopy utilize ionizing radiation to capture static or real-time images, respectively, of internal anatomic structures. Angiography refers to a fluoroscopic technique for evaluation of blood vessels via injection of iodinated contrast agents. X-ray studies specific for male infertility evaluation include vasograms and seminal vesiculograms to rule out pelvic obstruction of the reproductive tract and venography for evaluation and treatment of varicoceles. Each of these studies are used selectively in male infertility evaluation.

Vasograms are most commonly employed during vasal reconstructive procedures to assess for downstream patency of the vas deferens and ejaculatory ducts. To perform a vasogram, a vasotomy is made in the operating room at the time of planned reconstruction and contrast injected antegrade with simultaneous fluoroscopy. Contrast should be visualized flowing through the vas deferens, into the ejaculatory duct, and entering the prostatic urethra. Sites of possible obstruction include the inguinal or pelvic vas deferens (often secondary to prior surgery) or ejaculatory duct. While some contrast may enter the seminal vesicles (SVs) with forceful injection, prominent filling of the SV suggests ejaculatory duct obstruction (EDO). Vasograms are not commonly used in current practice as obstruction can also be assessed with saline injection while assessing for back pressure or by passing the free end of a small monofilament suture until resistance is met. If distal pelvic obstruction is suspected preoperatively, imaging with transrectal ultrasound (TRUS) or MRI may obviate the need for vasography.

Seminal vesiculograms are similarly indicated for evaluation of distal obstruction, specifically at the level of the ejaculatory ducts. The study is performed by first placing a needle in the SV under TRUS guidance before injection of contrast and fluoroscopic evaluation. Useful in confirming the diagnosis of EDO, a seminal vesiculogram can also evaluate real-time treatment efficacy after transurethral resection of the ejaculatory ducts (TURED). Immediately following resection, contrast is injected again into the SV to ensure patency as evidenced by free flow across the resected duct.

Varicoceles represent a common etiology of male subfertility and can be found in approximately 15% of the general male population (Gorelick and Goldstein, 1993). The prevalence rises to 30% in men presenting with primary infertility and up to 80% with

Fig. 1 Endovascular coils in the retroperitoneal left gonadal vein following varicocele embolization, note angiography catheter still present within upper gonadal vein.

secondary infertility. As the testicular veins enter the spermatic cord, they divide into a plexus of veins comprising the pampiniform plexus. These veins dilate excessively with Valsalva or upright positioning, causing retrograde blood flow back to the testis and palpably enlarged veins. Venography is an angiographic study utilizing fluoroscopy to image veins after the injection of contrast with the presence of large refluxing veins being diagnostic of a varicocele. While the most sensitive and specific test for varicocele diagnosis, venography is also the most invasive ([Jurewicz and Gilbert, 2016](#)). It is most useful in complex varicocele recurrences and is often performed in conjunction with angioembolization treatment where endovascular metal coils or sclerosing agents are deployed through percutaneous venous access to embolize, or block, a varicocele ([Fig. 1](#)). Risks to embolization include back pain, vascular injury, and coil migration. There is also a slightly higher risk of varicocele recurrence following embolization as compared with the current gold standard microsurgical subinguinal repair ([Halpern et al., 2016](#)).

Computed Tomography

CT similarly utilizes ionizing radiation but does so as the patient passes through a scanner, capturing X-rays from different angles and reformatting into axial, coronal, and sagittal images. MRI offers superior soft tissue resolution compared to CT, therefore it is not commonly used in male infertility evaluation. CT has a specific role in cross-sectional imaging for cases of nonreducing or solitary right varicoceles to rule retroperitoneal pathology which may be compressing the gonadal vein.

Ultrasound

The most common imaging modality used in the evaluation of male infertility is US owing to its low risk, minimal invasiveness, and overall cost effectiveness. US employs sound waves traveling through tissues at different speeds and reflected by interfaces back to a receiver to create a two-dimensional image. Increasing US frequency improves image resolution while sacrificing the depth of sound wave penetration (thus better for structures closer to the skin). US transducer arrays can be arranged in linear, curved, or other patterns for the desired application and probes built with one or more arrays in appropriate shapes for the anatomy of interest. Specific to male infertility, US can effectively evaluate testicular characteristics, ejaculatory duct patency, prostatic pathology, and penile vascular parameters in cases of erectile dysfunction.

Scrotal ultrasound

Scrotal US includes evaluation of the testes, epididymides, spermatic cord, vessels, and other scrotal structures. During the study, the scrotum is elevated on a towel or blanket and scanned with a high frequency (7–14 MHz) linear array transducer. Vascularity can be assessed with power and color Doppler flow modalities. Color Doppler imaging utilizes the Doppler effect to calculate fluid flow rate (usually blood) and displays flow in two colors, one signifying flow toward the probe and the other away. Power flow uses a single color to demonstrate flow within an organ with a monochromatic gradient to reflect the intensity of the flow rate.

Initial assessment of the testes should include measurements of the dimensions of each testis with total volume estimated using the Lambert formula ($L \times W \times H \times 0.71$). Size is not surprisingly correlated to the level of spermatogenesis since it is estimated that 85% of testis volume is involved in reproduction (Jurewicz and Gilbert, 2016). Normal testicular volume ranges from 15 to 25 cm³ with testicular atrophy diagnosed in many men with oligospermia or azoospermia. The echotexture of testicular parenchyma is normally smooth and homogeneous. Testicular tumors on the other hand appear as a discrete solid mass with heterogeneous features and are often palpable on physical examination. Some tumors may be incidentally discovered at the time of infertility evaluation given the known association with decreased semen parameters.

Microlithiasis refers to the presence of many echogenic foci within the testicular parenchyma creating a classic “starry sky” appearance (Fig. 2). While the etiology is unclear, microlithiasis is more commonly found in cases of male subfertility including testicular atrophy, cryptorchidism, and Klinefelter’s syndrome. Histologic review demonstrates calcification involving the seminiferous tubules which may underlie the relationship with reduced male fertility (Jurewicz and Gilbert, 2016). Concomitant testicular malignancies were noted in historical studies and thus microlithiasis was initially thought to be a risk factor for cancer development. Further research however has demonstrated that there is no evidence that microlithiasis represents a premalignant lesion and continued surveillance is no longer recommended (Jungwirth et al., 2012).

As with renal imaging, the increased availability of scrotal US has resulted in a greater frequency of incidental findings such as small testicular masses (STMs). Several series have shown that these subcentimeter hypoechoic lesions (Fig. 3) are typically benign

Fig. 2 Testicular microlithiasis present diffusely in bilateral testes on longitudinal (*left*) and transverse ultrasound (US) images (*right*).

Fig. 3 Incidental intratesticular 5 mm hypoechoic lesion noted on male infertility evaluation with scrotal US.

and can be followed safely with surveillance strategies (Bieniek et al., 2015bb). If removed, many of these lesions prove to be Leydig cell tumors on final pathology, both in infertile and general populations. Maximal lesion size ≥ 5 mm with internal vascularity may suggest increased risk of malignancy. Contrast-enhanced US is a newer technique which uses injection of an air bubble solution with real-time imaging to create a contrast form of US imaging. This modality has a high predictive value for identifying malignancy among STMs, but hyperenhancement was not present in some malignant lesions in one study, suggesting that it is not ready for implementation in testicular imaging yet (Lock et al., 2011). Adrenal rests also present as intratesticular hypoechoic lesions in cases of untreated congenital adrenal hyperplasia (Jurewicz and Gilbert, 2016). US imaging additionally helps with tumor localization (via preoperative needle placement or intraoperative surgical guidance) when considering a partial orchiectomy in cases of STMs, solitary testis, or bilateral lesions. Partial orchiectomy allows for maximal testicular tissue preservation for testosterone production and spermatogenesis.

In assessing the testicles, the goal is not only to determine imaging characteristics but also to assess the underlying function such as spermatogenesis. Localization of focal sperm production may further assist with guidance for testicular sperm extraction in men with nonobstructive azoospermia (NOA). Focal areas of increased blood flow have been postulated to reflect underlying spermatogenesis with one study confirming increased sperm retrieval rates with US-directed biopsies (Nowroozi et al., 2015). Elastography is another novel US modality which evaluates internal tissue elasticity and offers additional diagnostic information. The elasticity of testicular tissue was studied in a sample of azoospermic men and a scoring system created with scores ≥ 3 out of 5 correlating with NOA diagnosis (Li et al., 2012).

The epididymides are bilateral tubular structures running longitudinally along the posterior aspect of the testicles and are involved in sperm transport and maturation. On US, they commonly contain anechoic rounded structures representing epididymal cysts. When these cysts contain sperm, they are referred to as spermatoceles. Solid masses within the epididymides are typically benign adenomatoid tumors though patients with von Hippel-Lindau syndrome classically present with epididymal papillary cystadenomas. Inflammation or infection involving the epididymis, also known as epididymitis, is often heralded by enlargement and increased epididymal vascularity. Though not often found at the time of infertility evaluation, a history of epididymitis may indicate scarring and obstruction contributing to a man's fertility struggles.

The spermatic cord is made up of testicular arteries, veins, vas deferens, and numerous lymphatics and is evaluated as part of a routine scrotal US study. As discussed previously, the internal spermatic veins form the pampiniform plexus within the upper scrotum and extend into the inguinal canal before traveling through the retroperitoneum and inserting into the left renal vein or inferior vena cava on the left and right, respectively. A varicocele is defined as palpably abnormal dilation of the pampiniform plexus (often described as a "bag of worms") present when a patient performs a Valsalva maneuver. Varicoceles are graded clinically as grade 1 which is palpable with Valsalva only, grade 2 which is easily palpable, or grade 3 which is visible before examination.

Present in many men presenting with infertility, varicoceles are typically found on the left side or bilaterally, rarely on the right side only. The difference in laterality is thought to be secondary to the longer length of the left gonadal vein and the angle of insertion into the renal vein creating greater flow resistance. Incompetent or absent venous valves allowing for retrograde flow is also theorized as a possible cause of varicoceles. Varicoceles may negatively impact sperm parameters, cause scrotal pain, or create an unwanted cosmetic appearance. Adolescent varicoceles specifically can retard testicular growth during puberty resulting in hypotrophy. The negative effects on spermatogenesis are thought to be secondary to increased testicular temperature (compromised countercurrent heat exchange), tissue hypoxia, increased reactive oxygen species, and reflux of testicular and adrenal metabolites (World Health Organization, 1992).

The US appearance of varicoceles is characterized by hypoechoic or anechoic tubular structures within the spermatic cord with reversal of flow on color Doppler imaging (Fig. 4). The maximal vein diameter with Valsalva, number of enlarged veins (single or multiple), and presence of retrograde flow with provocative maneuvers should be noted. The cutoff for enlarged vein diameter is somewhat debated but most groups agree that a maximal dimension > 3 mm with Valsalva defines a varicocele (Jungwirth et al., 2012). While clinical varicocele grade has been correlated with degree of spermatogenesis impairment, subclinical varicoceles found on US only are not clinically meaningful. Some data, however, has revealed that among palpable varicoceles a maximal vein size > 3.5 mm may be related to improved postvaricocelectomy outcomes as compared to maximal vein size < 3.5 mm (Bieniek et al., 2015aa). The ultimate role of US in varicocele evaluation remains to be defined but it should be considered for patients with difficult examinations, often secondary to body habitus, or for confirmation of a varicocele before treatment decision making according to the AUA guidelines (Jarow et al., 2010).

Penile Doppler ultrasound

Erectile dysfunction is defined as the persistent inability to achieve or maintain erections for completion of satisfactory sexual activity. ED can be secondary to a variety of etiologies with many cases resulting from vascular impairments such as arterial insufficiency or veno-occlusive dysfunction. Imaging evaluation of ED serves to differentiate vascular from nonvascular etiologies via a penile Doppler US study. The study requires induction of an erection, usually by intracavernosal injection of a vasodilatory medication such as alprostadil, papaverine, phentolamine, or some combination thereof. The cavernosal arteries are scanned at baseline and every 5–10 min until the induction of a fully rigid erection. The peak systolic velocity, end-diastolic velocity, and resistive index of each cavernosal artery should be evaluated. Normal peak systolic velocity should be > 35 cm s⁻¹ while end-diastolic velocity should be < 0 cm s⁻¹ indicating good blood flow into the penis to create an erection and adequate blood trapping to maintain it. Standard grayscale images may be obtained for evaluation of penile plaques, priapism, and other rare conditions such as possible penile fracture.

Fig. 4 Prominent left varicocele with numerous dilated veins superior (*top left*) and adjacent (*top right*) to the testis on US with measurement of increased vein diameter with Valsalva (*bottom*).

Transrectal ultrasound

A TRUS involves the placement of a transrectal probe for evaluation of male pelvic anatomy including the prostate, SVs, ampulla of the vas, ejaculatory ducts, and bladder neck. This study is especially useful for men with semen analysis findings suggestive of partial or complete EDO including low ejaculate volume, oligospermia or azospermia, acidic pH, and low or absent fructose levels (Jarow et al., 2010). Before performing a TRUS, the patient is asked to complete an enema to evacuate stool from the rectum to improve image quality. The patient is then positioned in lateral decubitus or lithotomy position and a transrectal probe inserted. Transrectal probes usually contain single or multiple linear or curved arrays in the 6–9 MHz frequency range.

It is important to evaluate for the presence of the SVs since they have a common Wolffian duct embryologic origin as the vas deferens and epididymis. Unilateral or bilateral absence of the vas deferens is typically associated with corollary absence of the SV and ampulla of the vas deferens. Rarely, men with a thin or atretic scrotal vas deferens may have absence of more distal structures due to abnormal embryologic development. Unfortunately there are no reconstructive options to repair congenital absence of the vas deferens but sperm retrieved from the epididymis or testicle can be successfully used with assisted reproductive techniques.

TRUS should evaluate for signs of EDO and possible etiologies including congenital (prostatic or ejaculatory duct cysts) and acquired (infections, stones, postprocedural stenosis) conditions. Routine sonographic evaluation of the prostate should also include review of the peripheral zone for any suspicious hypoechoic lesion suggestive of prostate cancer and any evidence of central zone nodular enlargement corresponding to benign prostatic hyperplasia. Prostatic cysts which may contribute to EDO include utricle and Müllerian duct cysts which are typically found in the midline and ejaculatory duct cysts which are located in a paramedian location. The ejaculatory ducts can be found alongside the verumontanum and should be <2.3 mm in maximal width on US (Smith et al., 2008). Dilation of the ejaculatory ducts, while not diagnostic, suggests an underlying obstruction (Fig. 5).

Obstruction of the ejaculatory ducts additionally results in dilation of the SVs with a transverse measurement >1.5 cm suggestive of obstruction (Smith et al., 2008). In unclear cases, functional tests for EDO such as ductal chromotubation or SV aspiration and vesiculography (discussed above) may be pursued. These tests increase specificity at the cost of increased invasiveness. TRUS-guided needle placement into the SV allows for fluid aspiration and microscopic evaluation for the presence of sperm, not normally found in the SVs. Aspirated sperm can be cryopreserved while planning further treatment choices. Duct chromotubation and seminal vesiculography similarly involve needle placement into the SV and injection of colored dye (diluted methylene blue) or contrast agent

Fig. 5 Isolated left ejaculatory duct obstruction (EDO) confirmed on TRUS in transverse (*top*) and sagittal (*bottom*) images (wide arrow indicates obstructed duct in cross section, thin arrow points to “beaking” of obstructed distal duct).

injection, respectively. Each test can be performed for diagnosis and effective treatment evaluation following transurethral resection. Intraoperative TRUS is likewise suggested for transurethral resection of prostatic cysts to provide real-time guidance for improved safety and efficacy.

Retroperitoneal ultrasound

The retroperitoneal organs, in particular the kidneys, are located deeper within the body compared to the other genitourinary organs and are best evaluated with a lower US frequency setting of 2–5 MHz and a curved array probe. Positioning of the kidneys behind the lower ribs and under the diaphragm requires additional maneuvers for imaging including lateral positioning and breath holding. The AUA recommends evaluation for presence of congenital renal abnormalities in patients with Wolffian duct abnormalities such as congenital unilateral (CUAVD) or bilateral (CBAVD) absence of the vas deferens (Jarow et al., 2010).

During embryologic development, the ureteric bud emanates from the distal aspect of the Wolffian duct and improper regression of these structures can result in abnormalities of both the reproductive tract and ipsilateral kidney. Mutated cystic fibrosis genes can also be associated with congenital absence of the vas deferens but the kidneys are normally present in such cases. Renal agenesis is more commonly found with CUAVD than CBAVD though it occurs in a minority of such cases overall (Schlegel et al., 1996). Due to the possible association however, renal US is recommended for all patients with an absent vas deferens. In addition to renal evaluation, retroperitoneal US can assess for other retroperitoneal masses or lesions that may compress the gonadal vein and result in a varicocele. Imaging with CT or retroperitoneal US should be considered for any nonreducing or solitary right varicoceles.

Magnetic Resonance Imaging

MRI remains the most invasive and expensive imaging choice but offers superior soft tissue contrast, especially for male infertility evaluation involving cranial and pelvic anatomy. MRI works by inducing an oscillatory high strength magnetic field which reorients protons within tissues. As the field is turned off, the excited protons return to their resting state, emitting a radiofrequency signal measured by the receiving coil. These signals can be differentially processed to create standard T1, T2, and other sequence images.

Fig. 6 Pelvic and abdominal MRI images in patient with Zinner syndrome demonstrating left SV cyst (*top left, wide arrow*) with ectopic ureteral remnant (*thin arrow*), dilated left ejaculatory duct (*top right, arrow*), and left renal agenesis (*bottom*).

Cranial MRI is useful in cases of hypogonadism with elevated prolactin to evaluate for pituitary adenomas. An adenoma typically causes significant prolactin elevation, at least multiple times the normal upper reference range value. Hyperprolactinemia inhibits pulsatile GnRH release resulting in decreased gonadotropin levels and downstream testicular signaling for testosterone production and spermatogenesis. Microadenomas may be amenable to medical management but macroadenomas should be referred for appropriate surgical evaluation.

When evaluating pelvic anatomy with MRI, the magnetic field strength is an important consideration. A higher strength magnet such as 3 Tesla should be utilized for improved image resolution. The use of an endorectal coil should be avoided if possible as it can compress and obscure pathologies, not to mention the intrinsic patient discomfort. An MRI study may be particularly useful to rule out an intra-abdominal testis in adult men presenting with an absent testicle and an unclear pediatric surgical history.

Pelvic MRI has been studied for the diagnosis of EDO but rates of detection were found to be similar to that for TRUS ([Engin et al., 2000](#)). Study authors suggested that MRI be reserved for complex or unclear cases such as men with Zinner syndrome. Zinner syndrome is a triad of Wolffian duct anomalies including renal agenesis, ipsilateral EDO, and SV cyst ([Fig. 6](#)) which can lead to subfertility, sexual dysfunction, or pelvic pain. Due to its rarity, Zinner syndrome has only been reported in small series with treatment typically consisting of either TURED or SV cyst excision. MRI can assist with surgical planning in similar challenging cases.

Conclusions

Medical imaging augments our diagnostic abilities for specific etiologies of male infertility incompletely evaluated with basic physical examination and laboratory testing. The most commonly used imaging modality is US, particularly scrotal and transrectal studies, for evaluation of varicoceles and reproductive tract obstruction. Specific attention should be made to rule out congenital anomalies which may affect a man's overall general health or be passed along to offspring. Certain treatment options such as SV aspiration, TURED, or varicocele embolization may also be performed with real-time imaging guidance to improve procedural safety and efficacy.

ENVIRONMENT

Overview: Environment and Male Reproductive Medicine

Samuel Ohlander, University of Illinois-Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

The preceding chapters focused on the clinical evaluation of the male, highlighting diagnostic methodology to uncover pathophysiological abnormalities and their contributions to reproductive function. There is a broad range of historical information and examination criteria that a reproductive physician must consider in determining a male's reproductive fitness. We must not only consider the anatomic and physiologic make-up of the couple, but also the influences of their environment.

Human population exists across all cultures and climates, yet there are certainly aspects of regional lifestyle and vocational practices, such as diet, exercise, stress, shift work, and chemicals, that contribute to subfertility and adverse reproductive health. Similarly, the detrimental effects of obesity and malignancy on seminal quality are well established. This section will highlight the impact of industrial, agricultural, and technological evolution. Over the course of the last 40 years, seminal quality has dramatically decreased while the world has evolved. A recent meta-analysis reported a greater than 50% decline in total sperm count in Western men, unselected by fertility since 1973 (Levine et al., 2017). In a sense, we will be discussing the way that human kind has contributed to its own reproductive struggles.

The following chapter will focus on chemical exposures. While a basic understanding that certain chemicals can have an adverse effect on the testicles has existed for hundreds of years, our current knowledge remains limited. It is extremely difficult to control both the environment and the individual, and thus much of our scientific understanding of gonadotoxants is extrapolated from animal studies rather than well-constructed randomized, controlled human trials. Fortunately, male reproductive development and function is similar across species allowing for such inferences.

Increased public interest has stimulated greater investigation into chemical exposures. Researchers have identified directly gonadotoxic factors that impacted spermatogenesis, as well as parental insults that impacted fetal reproductive development in the womb. Colborn's proposed theory of endocrine-disrupting chemicals suggests that parental exposures to endocrine-disrupting chemicals impacts childhood development more than genetics (Colborn et al., 1993).

Yet not every cytotoxant has an adverse effect on reproductive development and function. Fortunately, the male anatomy contains a blood-testis barrier that is highly efficient at protecting testicular germ cells. The chemicals that we will discuss are those with properties allowing them to traverse the blood-testis barrier, or alternative means of reproductive insult, such as disruption of the endocrine axis.

Later chapters will focus on electromagnetic radiation and heat. With technologic evolution, public concern continues to rise over the potential adverse effects of electromagnetic waves from cell phones, computers, and other wireless devices. Due to the limited literature, controversy exists, but some observational studies have demonstrated dose dependent decreases in sperm quantity and quality. Along with the portability of technology has come a change of our workspace. People are no longer tied to electricity and desktops, but rather work from their laps. Given the highly temperature dependent environment of the testicle, much concern surrounds hyperthermia from portable devices.

While the type of the gonadotoxant or insult matters, often the reversibility of such exposures depends on timing, dose, potency, duration, and frequency. Pre-pubertal insults often impact the inherent development of the testes, leading to permanent damage, whereas adult exposures often may be reversed with removal of the insult. Most adult exposures contain a dose, potency, duration, or frequency dependent impact that dictates reversibility. Later chapters will discuss the relevance of exposures in greater depth.

Though not focus within this section, the contributions of lifestyle and personal habits on reproductive health are incorporated in the discussion throughout this volume. Most factors (diet, exercise, stress, smoking, alcohol) influence general health, which can then indirectly impact reproductive health.

Despite our incomplete understanding on much of the exact etiology, there is a general awareness of the potential detrimental health impacts from our ever evolving environment. We must continue to invest in well-designed studies to increase our knowledge, as subfertility and sexual dysfunction correlate to decreased quality of life.

Male Reproductive Toxicants: Electromagnetic Radiation and Heat

Beneranda S Ford-Glanton and David A Melendez, Saint Louis University, Saint Louis, MO, United States

Introduction

Human population in today's world lives surrounded by radiofrequency fields (RF) and electromagnetic radiation (EM) fields, transmitting almost all forms of electronic communication and data that humans produce every second. Mobile devices and laptop computers are EMR-emitting devices. The effect of mobile phone emitted radiation and heat on fertility is the subject of recent interest and investigations. Many studies have found a decrease in semen quality which has increased the focus on male reproductive health. Infertility affects approximately 15% of couples of reproductive age, and nearly half of these cases are linked to male fertility (Sharlip et al., 2002). Different harmful environmental influences have led to changes in semen analysis standards by reducing the lower limits of normal ranges, which were declared by the World Health Organization (2010). The possible negative impact of mobile phone radiation on sperm quality has been well established. While no certain conclusions can be drawn from current evidence, a growing number of studies indicate a decrease in male fertility associated with increased cellular phone usage (Agarwal et al., 2011) and laptop computers using Wi-Fi (Avendaño et al., 2012a). Here we review the current evidence regarding the effects of electromagnetic radiation and heat in male fertility.

Electromagnetic Radiation (EMR)

Modern society is ruled by the widespread use of mobile devices and computers and laptops with Wi-Fi function. It is nearly impossible to imagine our world today functioning without the use of these devices. Radiofrequency (RF) fields are part of the electromagnetic spectrum and are generally defined as covering the range of frequencies from 100 kHz to 300 GHz. Mobile phones use radio frequency waves, which are electromagnetic fields and, unlike ionizing radiation (e.g., X-rays and gamma rays) cannot break chemical bonds or cause ionization in the human body and therefore are less harmful. These are also known as forms of nonionizing radiation. However, there is evidence that suggests that sperm exposed to EMR can lose fertilizing abilities. Studies showed that specimens of human sperm exposed to EMR in a controlled setting had a decrease in rapid progressive sperm from 13% to 9%; a decrease in slow progressive sperm from 44% to 34% and an increase in immotile sperm from 36% to 51% (Erogul et al., 2006).

Mobile Phones as Toxicant to Fertility

Electromagnetic radiation emitted by mobile phones is one of the environmental toxicants that is capable of compromising male fertility by inducing a state of oxidative stress in the testes. This means that the ability of the testes to detoxify this type of radiation is impaired and the accumulation of these toxicants can cause cumulative damage. A correlation has been established between mobile phone radiation exposure, DNA-fragmentation level and decreased sperm motility (Gorpinchenko et al., 2014). The exact mechanism of the EMF interactions with our body is still controversial, although a few studies have suggested the involvement of degeneration of fats and the subsequent creation of highly reactive molecules in our body (Watanabe et al., 1997), as well as biochemically induced oxidative stress. Although the radio waves of cellular phones do not have enough energy to cause the ionization of atoms and molecules, the recent concerns over long-term exposure to the EMR emitted by mobile phones and other devices should be taken more seriously given the growing trend toward deterioration of the male germ line (spermatogenesis and sperm maturation) (Aitken and Koopman, 2004). The findings of Kesari et al. (2011) on antioxidants, malondialdehyde, histone kinase, micronuclei, and the sperm cell cycle are clear indications of an infertility pattern that is initiated due to an overproduction of cells that are already damaged. They also concluded that radiofrequency electromagnetic waves from commercially available cell phones may affect the motility and vitality of sperm.

Other studies suggest that people who use their cell phones >4 h a day may have lower sperm count and about 30% lower sperm motility than nonusers (Al-Damegh, 2012). Also, it was demonstrated that the percentage of normal sperm with no structural defects in high-level mobile users was half that of nonusers, and the rates of normal sperm with no defects were decreased with greater levels of cell phone use (Agarwal et al., 2008; Erogul et al., 2006). At the same time, sperm from long-time mobile users may have abnormal characteristics. Specifically, a study by Gutschi T, Mohamad Al-Ali B, Shamloul R, Pummer K, and Trummer H, compared the sperm of mobile users and nonmobile users. It was shown that 68% of the analyzed sperm from cell phone users had pathological morphology, compared to 58% of sperm from nonusers (Gutschi et al., 2011). Many men who talk on a cell phone using a Bluetooth device or other headset keep the phone in a pants pocket or clipped to a holster. This exposes their reproductive organs to cell phone radiation, and several studies have found lower sperm count and/or poorer sperm quality in men who use their phones this way than in those who do not (Kilgallon and Simmons, 2005).

Computers and Laptops: Toxicants to Fertility?

Laptops and computers use Wi-Fi to transmit data every second. These are EMR-emitting devices that have also been studied. Evidence suggests that prolonged use of these devices (> 4 h) can affect sperm motility and disrupt their DNA. [Avendaño et al. \(2012b\)](#) evaluated the effects of laptop computers, connected to local area networks through Wi-Fi, on human sperm. Their results demonstrated a significant decrease in sperm progressive motility and a significantly higher proportion of sperm with DNA fragmentation when samples were incubated for 4 h under the laptop. These differences were seen in comparison with portions of the same semen samples incubated under similar conditions, but outside the proximity of any computer or electronic device. The investigators speculated that the use of a laptop computer wirelessly connected to the internet and positioned near the male reproductive organs may decrease human sperm quality. Therefore, exposing the semen to radio frequency electromagnetic waves from laptops connected to the internet through Wi-Fi could have, basically, the same potential to damage spermatozoa as EMR emitted from a mobile phone.

The Effects of Heat

The testes are located outside the body to keep temperature below the core temperature, and it is well known that internal heating as in fever and external heating for short periods of time may result in a dramatic but temporary decrease of sperm count and other aspects of semen quality after a delay of some 6–8 weeks ([Mieusset and Bujan, 1995](#)). It is well documented that the sedentary work position is associated with an increased scrotal temperature. Men sitting at work for 8 h a day have on average 0.7°C increased scrotal temperature during the day in comparison with employees with < 8 h in the sedentary body position ([Hjollund et al., 2002](#)). Although an increase of scrotal temperature of this order of magnitude might be sufficient to impair the generation of sperm, reduced sperm count seems not related to sedentary work ([Rowley et al., 1974](#)). Likewise, it has been speculated that tight underwear could increase testicular temperature and a few studies have reported reduced sperm count related to the use of tight underwear and trousers, but with nonconclusive evidence.

There is no doubt that heat may affect male reproduction but whether heat exposures in current workplaces are of this magnitude is undetermined. The evidence for an adverse effect on male reproduction of several occupational and environmental exposures and toxicants, such as heat, ionizing radiation, inorganic lead, and welding operations is strongly supported in well-designed epidemiological studies. Occupational exposures have been divided into physical exposures (heat and radiation), chemical exposures (solvents and pesticides), psychological exposures (distress), and exposure to metals and welding.

An occupational exposure limit of 15 mSv per year has been adopted in several countries, and if this limit is not exceeded, testicular effects are unlikely. Millisievert is defined as the average accumulated background radiation dose to an individual for 1 year. Apparent testicular effects of high-frequency EMR (300 kHz–300,000 MHz including radar exposure and microwaves) that have been observed in earlier studies may result from testicular heating. So far, no consistent evidence indicates that nonionizing radiation interferes with male reproductive function unless the amount of energy is sufficient to disrupt testicular temperature regulation ([Jensen et al., 2006](#)).

EMR and Heat Effects: Irreversible?

EMR has a negative effect on testicular function through the creation of reactive molecules, or oxidative stress, and the concomitant disruption of the testicular ability to detoxify those molecules. Interestingly, few studies have evaluated the possible protective role of vitamins C and E in the EMR-induced oxidative stress in the testes, which may involve facilitating the restoration of normal testicular tissue and function ([Gorpinchenko et al., 2014](#)).

We know that testicular tissue is highly sensitive to ionizing radiation. Doses in the range of 0.11–15 Gy may temporarily reduce sperm counts, while 2 Gy may result in long-lasting or permanent absence normal sperm and sterility ([Rowley et al., 1974](#)). At higher doses (> 15 Gy), the Leydig cells, in charge of production and secretion of testosterone, may be affected. In addition, whole body irradiation can damage the regulation of hormones in the Brain, affecting the reproductive capability. However, more studies are necessary to evaluate if the additive effects of EMR-emitting devices and nonionizing radiation in sperm counts are reversible or irreversible. None of the above-mentioned studies have evaluated prospectively the influence of EMR irradiation on paternity. Such investigations require long-term design and many previously healthy volunteers. At the present time nobody knows the real intercommunication between the constant direct mobile phones, computers, laptops, and Wi-Fi-emitted irradiation effects on testes and developmental delays in the offspring.

Conclusion

Collectively, the research indicates that exposure to EMR radiation and heat may lead to decreases in sperm count, sperm motility, and vitality, as well as increases in indicators of sperm damage such as higher levels of reactive oxygen species, oxidative stress, DNA damage and changes in sperm morphology. However, there is no consensus on how these findings may affect human fertility in the years to come and if the effects caused by EMR and heat are reversible or irreversible. Well-designed investigations are needed to

evaluate the real consequences of long-term employment of EMR-emitting devices and long-time exposure to heat. Additionally, there are no published studies examining the effect of EMR radiation and heat on reproductive health in women. Such studies are much more difficult to carry out, since they often require invasive techniques. While it is certain that the evidence show a negative effect of radiofrequency fields (RF) and electromagnetic radiation (EM) fields on sperm studies, it is also evident avoidance of daily exposure to these invisible toxicants might be impossible in our time. Current recommendations should focus on limiting the amount of time we spend using our mobile phones, laptops and computers, especially during periods of times that couples are trying to conceive a child.

GENETICS

Overview Genetics and Male Reproductive Medicine

Robert D Oates, Boston University School of Medicine, Boston, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Congenital bilateral absence of the vas deferens The clinical condition resulting from an absence of the reproductive ductal structures that transport sperm from the testis to the ejaculate.

Intracytoplasmic sperm injection An advanced reproductive technique where an individual sperm is micro-injected into the cytoplasm of a harvested egg.

Klinefelter syndrome A constellation of infertility and mild hypogonadism resulting from an extra X chromosome being present, the karyotype is 47,XXY.

Primary ciliary dyskinesia A group of disorders manifested by, as one component of many, defects in sperm movement.

Y chromosomal microdeletion A small piece of the long arm of the Y chromosome is missing and the genes involved in sperm production that reside in that stretch are as well.

Introduction

Many cases of male reproductive deficiency were considered uncorrectable and the patient was deemed “sterile.” Evaluation was limited, not only by lack of any therapeutic options, but also by a dearth of any etiologic knowledge. However, the development of ever sophisticated and powerful advanced reproductive techniques (ART) provided treatment opportunities for some of these men, which coincided temporally with curious individuals coming into the nascent field of male reproductive medicine and surgery. The novel information and strategies to investigate and explore the human genome helped fuel studies trying to determine, as best possible, the genetic underpinnings of the conditions that were now being “treated,” or at least, compensated for. Was it appropriate, would the health of any conceived offspring be affected, does the genetic anomaly confer other health risks? All of these types of questions beg for answers and the field has moved steadily, if slowly, forward in trying to provide those answers.

Specific Chapters

Male reproductive deficiency can be due to defects in sperm production, defects in sperm quality (structure and/or function), defects in sperm transport through the reproductive ductal system or sperm genetic/epigenetic abnormalities limiting fertilization of embryo development ([Harnisch and Oates, 2012](#)). Each chapter in this section will touch on these, displaying the wide variety of diverse etiologies and presentations of male reproductive compromise.

Numerical chromosomal anomalies like Klinefelter syndrome (47,XXY) are actually quite common when looking at the causes of azoospermia and will be fully explored in Chapter Sperm Defects while Chapter Immunological Male Subfertility will detail the structural chromosomal defects that are also found in men with severe oligospermia or recurrent miscarriage ([Oates, 2012](#)). It is a common theme throughout these chapters that it is important to have determined the genetics behind the male’s reproductive deficiency prior to blindly just looking for sperm surgically or using ejaculate sperm as a male gamete source for advanced reproductive techniques. This can be no more clear than what will be described in Chapter Medical Conditions and Male Reproductive Medicine: An Overview—the *a priori* knowledge of an *AZF**a* or *AZF**b* microdeletion predicts that no sperm will be found on testicular exploration and that any invasive surgical options are not warranted or helpful for the couple. In addition, offspring health must always be viewed as important a concern as patient success. For example, when a man has an *AZF**c* microdeletion as the proximate cause of his sperm production deficiency, all sons will inherit this Y chromosome and will experience reproductive failure in their own future ([Rozen et al., 2012](#)).

Chapter Overview Treatment and Male Reproductive Medicine explores the connection of congenital bilateral absence of the vas deferens (CBAVD) and mutations in the “Cystic Fibrosis” genes ([Yu et al., 2012](#)). An odd association, it seems, but one well-grounded in molecular and cellular physiology. As will be discussed, before undertaking an ART cycle using harvested sperm, it is critical to understand the CFTR mutation status of both partners to prevent, if the situation was right for this, the birth of a child who will be burdened with the life-long morbidity (and mortality) of Cystic Fibrosis. Understanding the genetic basis of male

reproductive compromise is not about just answering the question of “why,” it is also about obtaining critical information to proactively and prospectively assist clinicians and couples attempting to navigate the trying and difficult world of infertility to have a healthy child. Chapters Paternal Age and Fertility Concerns and General Endocrine Therapy also describe anatomical abnormalities which can be responsible for failure of sperm transport to the ejaculate or even the success of coitus and intravaginal deposition of sperm (Van Batavia and Kolon, 2016).

A proper functioning endocrine system is critically important to optimizing sperm production and the other components necessary for male reproductive competency (libido, erection, and ejaculation). Both chapters Varicocele: Evaluation and Pathophysiology and Endocrine Stimulatory Therapy for Testis Sperm Extraction will explore the genetic determinants of disorders of the hypothalamic-pituitary axis and the consequent effect on male fertility (Dwyer et al., 2013).

Spermatozoal movement and ability to fertilize a waiting oocyte may be impaired to such a dramatic degree that the male (and couple) are rendered infertile. Some of these conditions can be overcome with technology while others are not. Chapters Medical Non-Endocrine-Targeted Therapies: Ejaculatory Dysfunction and Immunotherapy and Empiric Infertility Treatment will review these types of conditions, such as primary ciliary dyskinesia and globozoospermia in some detail (Davila Garza and Patrizio, 2013). Finally, the emerging field of epigenetics may herald an entirely new category of sperm deficiency that may not outwardly affect sperm number, sperm motility, sperm shape, sperm transport or sperm fertilizing ability. Rather, the earliest events of embryo formation and development are marred through heretofore unknown anomalies in the epigenome the sperm is delivering to the oocyte. Chapter Infectious and Inflammatory Male Infertility will enlighten the reader on this interesting field of inquiry (Jenkins et al., 2016).

Numerical Chromosome Abnormalities

Yetunde Ibrahim and James Hotaling, University of Utah, Salt Lake City, UT, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Human chromosomal abnormalities may be numerical or structural. Numerical chromosomal abnormalities or aneuploidies refer to an alteration in chromosomal number from the normal diploid and haploid complement of somatic cells and gametes respectively. These include trisomies, monosomies, triploidies and tetraploidies. On the other hand, structural chromosomal abnormalities include translocations, deletions and duplications. Aneuploidy can be either numerical or partial in nature involving either gain or loss of an entire chromosome. It is the leading cause of pregnancy loss and developmental disabilities in humans (Hassold and Hunt, 2001). It affects up to 5% of clinically recognizable pregnancies and it is estimated that up to 60% of conceptions are aneuploid but are spontaneously aborted even before a pregnancy is clinically recognized (Hassold et al., 1993).

Chromosomal aneuploidy typically occurs as the result of a meiotic nondisjunction event in gametes, precocious separation of chromatids or a post-zygotic mitotic nondisjunction event in the embryo (Hassold and Hunt, 2001; Hassold et al., 1993; Hassold and Hunt, 2009; Yanowitz, 2010; Fragouli et al., 2011; Gabriel et al., 2011; Kuliev et al., 2011) (Figs. 1 and 2). It has been established that advanced maternal age is the biggest risk factor for numerical chromosome abnormalities (Hassold and Hunt, 2009). Current knowledge suggests that most aneuploidy in early embryos is predominantly derived from female nondisjunction (~95%) or is mitotic in origin, with the exception of aneuploidy of the sex chromosomes which is paternal in origin in 50%–100% of cases (Tables 1 and 2; Hassold et al., 1993; Lue et al., 2001; Lanfranco et al., 2004; Herlihy et al., 2011; Abdel-Razic et al., 2012; Jacobs et al., 1965; Stochholm et al., 2006, 2012; Sarkar and Marimuthu, 1983; Tartaglia et al., 2010; Koeberl et al., 1995; Homer et al., 2010; Wilson et al., 1989; Suri et al., 1995; Hsu, 1996; Gunther et al., 2004; El Moussaif et al., 2011; Hsu, 1994; Peet et al., 1998; Patacchiola et al., 2012; Gropman et al., 2010; Tartaglia et al., 2011; Kassai et al., 1991; Ricci et al., 1968; Wood et al., 2011).

Nowadays, the advent of preimplantation genetic screening in addition to in vitro fertilization has enabled chromosomal complement of cultured embryos to be determined and allows for the selection against aneuploid embryos for embryo transfers. However, this technology is imperfect as there have been reports suggesting that on rare occasions, an embryo deemed aneuploid via testing but subsequently transferred resulted in a live birth without any chromosomal abnormality (Greco et al., 2015; Gleicher and Orvieto, 2017).

The following sections will summarize our current knowledge of numerical chromosomal abnormalities that impact male reproduction, some non-reproductive implications of these abnormalities, screening guidelines and potential future directions using our current technology.

Fig. 1 Meiotic nondisjunction event.

Fig. 2 Mitotic nondisjunction event.

Table 1 Numerical sex chromosome abnormalities

<i>Aneuploidy</i>	<i>Major clinical manifestations</i>	<i>Reproductive implication</i>
Klinefelter (47,XXY)	Tall stature, small testes, infertility	Infertile
47,XXY	Tall stature, mild delay in language and motor development	Most are fertile
Turner (45,X)	Short stature, facial dysmorphism, heart defects, streak gonads	Infertile
47,XXX	Most are physically normal. Some tendency to be tall	Most are fertile but premature ovarian failure can occur
45,X/46,XX Mosaic	Most common sex chromosome mosaicism. Milder clinical features of Turner	Some are fertile
45,X/46,XY Mosaic	Wide phenotypic spectrum with male phenotype being the most common presentation followed by ambiguous genitalia and lastly, female phenotype	Some are fertile, some have reduced fertility and some are infertile
49,XXXXY	Low nasal bridge with a wide or upturned tip, wide set eyes, epicanthal folds, skeletal anomalies, heart disease, severe hypogonadism, endocrine disorders	Infertile
49,XXXXX	Intellectual disability, craniofacial, cardiovascular and skeletal anomalies are variable	Infertile

47,XXY—Klinefelter Syndrome (KS)

This is a syndrome that occurs in approximately 1–2 in 1000 live births ([Morris et al., 2008](#)) and is the most common cause of azoospermia in men ([Bojesen and Gravholt, 2007](#)). KS accounts for about two thirds of all chromosomal abnormalities observed in infertile men ([De Braekeleer and Dao, 1991](#)).

Etiology

In Utero, the XXY fetal testes has the normal complement of primordial germ cells. Due to a defect in Sertoli cells and germ cell communication during testes maturation, progressive loss of germ cells occurs during childhood such that by adulthood, no germ cells remain ([Lue et al., 2001](#)). In theory, the etiology of the nondisjunction in Klinefelter can be from maternal meiosis I or II or paternal meiosis II. You would expect that each of these situations would contribute to 33% of cases. However, nearly 50% of Klinefelter patients show a paternal origin ([Thomas and Hassold, 2003](#)) with some studies showing an increased frequency with advanced paternal age ([Lanfranco et al., 2004](#)).

Presentation

The spectrum of KS presentation is wide but all males with KS have small testes (<10cm³) and significantly elevated follicle stimulating hormone (FSH) and luteinizing hormone (LH). In early life, KS may be diagnosed in boys with behavioral disorders and long legs. It is important to distinguish KS from other forms of eunuchoidism that result in both long upper and lower extremities. The IQ of patients with KS typically falls within the normal range but tends to be lower than that of other siblings. Most patients present as adolescents with small firm testes and hypogonadism with varying degrees of androgen deficiency. Later in life, many males present at infertility centers with azoospermia ([Lanfranco et al., 2004](#)). Although interestingly, men with KS almost always have normal libido and no evidence of erectile dysfunction. Other non-reproductive sequela manifested in patients

Fig. 3 Phenotype and Karyotype of a patient with Klinefelter syndrome.

with KS include expressive language difficulties, pulmonary diseases including bronchiectasis, chronic bronchitis and emphysema, systemic lupus erythematosus, varicose veins resulting in leg ulcers, hypothyroidism, metabolic dysfunction, osteoporosis, higher incidence of breast cancer, non-Hodgkin's lymphoma, extragonadal germ cell tumors and a decreased risk of prostate cancer (Anon, 1965; Volkl et al., 2006; Weiss et al., 2005; Swerdlow et al., 2005; Campbell et al., 1980; Scofield et al., 2008; Bojesen and Gravholt, 2007). Despite these wide array of clinical presentations, the exact mechanism behind many of these non-reproductive sequela remains unknown (Fig. 3).

Mechanism of Fertility Impairment

One reason for the wide phenotypic distribution of KS is that 10%–20% of men with KS are mosaics, typically 47,XXY/46,XY (Lanfranco et al., 2004). The greater the number of X chromosomes, the greater the phenotypic consequences, both gonadal and extragonadal (Paulsen et al., 1968). A small subset of non-Mosaic men with KS will have some sperm in their ejaculate. However, this does not translate to a normal hormonal profile as these men will still present with significantly elevated FSH levels in direct response to abnormal spermatogenesis. Likewise, LH levels are chronically elevated as the Leydig cells require maximal stimulation to produce testosterone. For these reasons, most men with KS have hypoandrogenism, and often hyperestrogenemia resulting in gynecomastia, which could increase in severity with age (Groth et al., 2013; Lanfranco et al., 2004; Oates, 2003; Wikstrom et al., 2006).

Implications of Non-reproductive Impairments

KS is a key risk factor for early-onset osteoporosis (Bojesen et al., 2011). The etiology is likely multifactorial but testosterone is thought to play a key role. It has been well defined that testosterone in men and estrogen in women play a vital role to bone health. Thus, in KS, testosterone deficiency can lead to decreased bone formation and resorption. Other possible mechanisms for osteoporosis in KS are abnormalities in CAG length, low levels of insulin-like factor 3 and X-chromosome inactivation (Ferlin et al., 2011; Wikstrom et al., 2006). Men with KS have also been shown to be susceptible to metabolic dysfunction including type 2 diabetes, decreased muscle, increased adiposity, decreased insulin sensitivity, decreased muscle strength and oxygen consumption capacity (Gravholt et al., 2011).

Diagnosis

The diagnosis of KS is usually made by determining the karyotype of peripheral leukocytes. Some mosaics will only be detected by karyotype of skin fibroblasts and occasionally of testicular biopsy specimen.

Management

Early detection of KS allows for early intervention for cognitive and behavioral disorders. Androgen replacement allows for development of masculine secondary sexual characteristics, improved self-esteem, strength and bone mineral density. With regards to fertility, the degree of testicular mosaicism is an important factor in determining spermatogenesis and fertility potential. The advent of intracytoplasmic sperm injection (ICSI) technology has led to an increased potential for fertility in patients with KS. Using testicular sperm extraction (TESE) technology, sperm can be successfully extracted from the testes and utilized in IVF/ICSI cycles. Results from this technology were however fraught with a high incidence of sex chromosome hyperploidy and autosomal aneuploidy in the sperm of Klinefelter men (Lim et al., 1999). A study by Yarali et al. demonstrated that pregnancy and implantation rates were comparable for a group of 33 patients with KS (39% and 23%) versus a group of 113 men with non-obstructive azoospermia and a normal karyotype undergoing TESE/ICSI (33% and 26%). Fertilization rates were also similar between the two groups. However, results from preimplantation genetic screening revealed that only 59% of the embryos from the KS patients had a normal karyotype (Yarali et al., 2009). Recently, a study by Vicdan et al. (2016) reported the ICSI outcomes using fresh and cryopreserved sperm obtained via TESE from azoospermic men with KS. In this group of 83 azoospermic men with KS, 24

live births were obtained. The authors found that the use of fresh and cryopreserved-thawed sperm in IVF/ICSI cycle outcomes were equally successful. In addition, no clinical or laboratory parameter predicted the presence of spermatozoa in patients with KS except the TESE procedure itself (Vidán et al., 2016). However, this study does not negate the concern over the increased risk of aneuploidy in KS men as it has been demonstrated that frequency of XY sperm, the main cause of aneuploidy in men with KS increases significantly with increasing paternal age (Arnedo et al., 2006). There is also evidence suggesting that spermatogenic potential decreases with advancing paternal age in men with KS (Aksela et al., 2006; Emre Bakircioglu et al., 2006; Foresta et al., 1999). This has led to the support of surgical sperm extraction through microTESE for sperm banking at a young age.

Trisomy 18p

Complete, isolated trisomy of the short arm of chromosome 18 is exceedingly rare. Only about 24 patients have been described in the literature (Orendi et al., 2013). This is caused by an unbalanced translocation involving the short arm of chromosome 18. Individuals with this rare syndrome have variable facial dysmorphism and mild to moderate cognitive impairment. A spermatogenic defect may be associated with Trisomy 18p. A recent case study reported on a 28-year-old male who presented with facial dysmorphism, mild intellectual disability and a symptom that had previously never been reported in the literature in this population; non-obstructive azoospermia. Cytogenetic analysis revealed an additional segment on the short arm of chromosome 14 (Jedraszak et al., 2015).

Unfortunately, the low numbers of reported cases of trisomy 18p makes it difficult to define a specific phenotype for this syndrome and it is possible that this finding of non-obstructive azoospermia in this one man is a chance event.

46,XX Testicular Disorder of Sex Development (DSD)

This is a very rare structural chromosomal aberration that affects 1/20,000 men with infertility (Ergun-Longmire et al., 2005). Although this syndrome will be covered in greater detail in another chapter, I have provided a brief review here due to similarities in phenotype with KS. The spectrum of individuals who are XX and have a disorder of sex determination have a range of phenotypes, from phenotypic males to all degrees of genital ambiguity. For the purpose of this article, we are focusing on patients with XX testicular DSD who are unambiguously male.

Etiology

The most common cause is an Xp:Yp translocation including SRY, the sex determining region, which initiates and maintains the male biologic program (Schiebel et al., 1997).

Presentation

Masculinized individuals with 46,XX DSD have been referred to as having *de la Chapelle syndrome*. There are some characteristics that are similar between men with 46,XX DSD and KS and these include small testes, azoospermia, gynecomastia and lack of secondary sexual characteristics. However, in 46,XX testicular DSD, phallus size is small to normal and patients have normal sexual function and intelligence (Bouayed Abdelmoula et al., 2003; Vorona et al., 2007).

Diagnosis

The diagnosis of 46,XX testicular DSD is often made during an investigation of infertility or delayed puberty. These patients have hypergonadotropic hypogonadism with elevated FSH and LH, decreased testosterone and dihydrotestosterone (DHT). FISH for the SRY gene can be performed and will be detected in 90% of phenotypic males with 46,XX testicular DSD.

Management

Phenotypic males with 46,XX testicular DSD who are SRY positive are not at increased risk for gonadoblastoma as they lack a complete Y chromosome. At puberty, most affected individuals require treatment with the male sex hormone testosterone to induce development of male secondary sex characteristics such as facial hair and deepening of the voice. Hormone treatment can also help prevent breast enlargement.

Reproductive Implication

46,XX DSD males are uniformly infertile because they lack the azoospermia factors (AZFa, AZFb, AZFc) required for normal spermatogenesis (Patrat et al., 2010). MicroTESE or other attempts at having biological children do not apply to these men. Referral to a genetic counselor is usually mandatory.

Genetic Screening

Genetic abnormalities can cause infertility by affecting sperm production or sperm transport. Structural chromosomal aberrations are up to 10 times more common in infertile men than fertile controls (3% in oligospermic men and 19% in men with non-obstructive azoospermia) (Bojesen and Gravholt, 2007; Chandley, 1998; Yoshida et al., 1997a,b). Men with nonobstructive azoospermia or severe oligozoospermia are at increased risk for having a genetic abnormality compared to fertile men. For these reasons, a karyotype is recommended by the American Society for Reproductive Medicine (ASRM), the American Urological Association (AUA) and the European Academy of Andrology (EAA) in all men with azoospermia or a total motile sperm count (<5 million/mL). Other guidelines, such as the international consortium of experts from 12 national scientific guidelines that produced a report in 2002, recommend a broader approach. They suggest offering a karyotype for men with a total motile sperm count below 10 million and for all couples who have not achieved a pregnancy after 1 year (Foresta et al., 2002). The tests consist of a gross examination of the autosomal and sex chromosomes and unfortunately, in the United States many insurance companies do not cover this expensive assay.

Looking Ahead: The Role of Preimplantation Genetic Screening

Preimplantation genetic screening (PGS) has revolutionized the field of reproductive medicine. Its goal is to detect de-novo aneuploidy and subchromosomal deletions and additions in embryos of couples undergoing IVF for subfertility reasons. Forty to sixty percent of preimplantation embryos are aneuploid and accounts for the most common embryo factor responsible for many implantation failures (Gianaroli et al., 1997). PGS allows for selection for euploid embryos and in theory, should reduce multiple pregnancy rates by allowing more efficient embryo transfer.

However, the hypothesis that PGS will improve implantations rates, pregnancy rates and live births while simultaneously reducing miscarriage rates has come under recent scrutiny. One of the essential assumptions surrounding the implementation of PGS over 20 years ago was that a single trophectoderm biopsy at the blastocyst stage is representative of the ploidy of the entire trophectoderm as well as the inner cell mass. This assumption fails to consider post-fertilization mitotic non-disjunction events, which can result in one embryo containing cells with different chromosomal complements i.e. a mosaic. While this issue is much less common nowadays because PGS is typically performed on blastocysts compared to cleavage stage embryos where the incidences of mosaicism are 3%–5% versus 50% respectively (Munne et al., 1994), the diagnostic accuracy is still not 100% (Dahdouh et al., 2015; Greco et al., 2015). The hypothesis is that even if PGS were to detect mosaicism, this does not necessarily mean that the fetus would be mosaic or abnormal as the biopsy may have removed those abnormal cells. Several reports have described healthy babies born after the transfer of embryos detected as aneuploid by PGS (Greco et al., 2015; Gleicher and Orvieto, 2017).

While this technology is imperfect, the incidence of mosaicism is still relatively low in blastocyst biopsies that it can be a significant tool in selecting against the transfer of embryos with numerical chromosomal abnormalities in subfertile couples undergoing IVF. We anticipate that with improvement in the current technology, we may be fortuitous and reduce the incidence of infants born with numerical chromosomal abnormalities within the subfertile population, which is already a population with a higher incidence of poor neonatal outcomes. We await further implementation of newer genetic tools and strengthening our current assays.

Y Chromosome Microdeletions

Ryan W Dobbs, Laurel Sofer, and Samuel Ohlander, University of Illinois at Chicago, Chicago, IL, United States

Introduction

Determining the nature of the storage, replication, and transmission of our genetic material has long been a source of fascination and investigation for scientists. Following the identification of chromosomes as the carriers of genetic material, there has been a revolution in our understanding of genetic principles that underlie inheritance and reproduction. In humans, the genetic code is comprised of 23 pairs of chromosomes: 22 paired autosomes and the sex chromosomes, the latter of which consists of either a paired XX chromosome in women or one X and one Y chromosome in men.

In the early 20th century, researchers discovered that sex determination was due to the presence or absence of the Y chromosome (Hotaling, 2014). From an evolutionary standpoint, the Y chromosome is highly efficient, transmitting the entire male phenotypic pathway in a highly conserved amount of DNA. The Y chromosome is exclusively transmitted in reproduction through sperm and has a high baseline mutation rate due to the multiple cell divisions occurring during gametogenesis and the highly oxidative environment of the testis. Unlike autosomes and the paired sex chromosomes of women, the Y chromosome does not have a “backup” or paired copy of critical genetic material and is vulnerable to passing on deleterious alleles (alternative forms of a gene arising from mutations) because it is unable to recombine during meiosis and is directly passed from father to son. The consequence of this is that any loss or deletion of genetic material in the Y chromosome may have a significant reproductive impact.

Y Chromosome

The Y chromosome is one of the smallest chromosomes with the least number of genes of any chromosome. It is made up of several regions: the pseudoautosomal region (PAR) which lies on the short arm of the Y chromosome (Y_p), and the heterochromatic and euchromatic regions which lie on the long arm (Y_q). The PAR regions exchange genetic material with the PAR region on the X PAR region during meiosis. PAR1 and PAR2, located on the telomeres of Y_p and Y_q , respectively, represent 5% of the chromosome whereas the majority of the Y chromosome is made up of the nonrecombining Y (NRY). The region includes the SRY gene. Also known as the Male Specific Y (MSY) chromosome, this portion does not recombine with the X chromosome and composes 95% of the Y chromosome. Because of the fact that the Y chromosome has only one copy of its critical genetic material, any deletion or mutation of this material may have a severe impact on a man’s spermatogenesis potential. Microdeletions may occur when two palindromic sequences of the Y chromosome recombine inadvertently, deleting the intervening genetic material (Hotaling, 2014). A diagram of the Y chromosome is shown in Fig. 1.

Y Chromosome Microdeletions

Y chromosomal microdeletions (YCM) represent a family of genetic disorders that arise from spontaneous mutations in the Y chromosome as described above, and which are passed from father to son (Hotaling, 2014). Broadly speaking, these YCM occur as a result of deletions within portions of the Y chromosome which are responsible for carrying the genetic information necessary for spermatogenesis. These deletions impact production of a number of proteins necessary for normal sperm development and as such, men with YCM clinically present with a range of spermatogenic failure from oligozoospermia to complete azoospermia with severe male factor infertility (Hopps et al., 2003). As genetic abnormalities are associated with an estimated 15%–30% of cases of male factor infertility (Hotaling, 2014), YCM represent a critically important subset of men presenting with infertility, and understanding these microdeletions is vitally important for the proper counseling and care of these men.

While the gold standard for diagnosis of YCM is whole DNA sequencing of a patient’s Y chromosome, presently this technique is too expensive for routine research or clinical purposes. Instead, patients with unexplained infertility can be screened by harvesting genomic DNA from blood or lymphoblastoid cells and mixing these DNA samples with a series of known genetic markers for

Fig. 1 AZF regions of the Y chromosome.

sequence tagged sites (STS) on the Y chromosome (Qureshi et al., 1996). These mixtures then undergo polymerase chain reaction amplification and gel electrophoresis. If a reaction fails to amplify following three amplifications, then the corresponding STS is considered to be absent and a YCM can be diagnosed. More recently, some investigators have described techniques with multiplex polymerase chain reactions to amplify several different DNA sequences to increase the speed and efficiency of YCM screening, detecting about 95% of microdeletions (Zhu et al., 2017).

Azoospermia Factor (AZF) Region Microdeletions

The most commonly implicated YCMs occur within a portion of the Y chromosome referred to as the azoospermia factor (AZF) region. Subregions within this AZF region located on the distal portion of the Y chromosome long arm are further divided into the AZFa (sometimes referred to as AZF1), AZFb, and AZFc (sometimes collectively grouped as AZF2) genes and serve critical functions in the production of sperm. An overview of AZFa, AZFb, and AZFc YCM are shown in Table 1. These deletions were first identified by Vogt et al. (1996), who identified a small subset of men with these specific YCM within a large cohort of men presenting for infertility evaluation. AZFa deletions remove two critical genes for spermatogenesis, USP9Y and DBY or DDX3Y. Loss of these genes result in absence of sperm and Sertoli cell only syndrome (Nutti and Krausz, 2008).

While the AZFb and AZFc regions were initially thought to be distinct, further investigation has demonstrated that these regions do have some overlap and may be deleted together (Hotaling, 2014). Microdeletions within different AZF regions have a profound impact on clinical outcomes and management. In a study of semen extraction by diagnostic testicular biopsy or testicular sperm extraction (TESE), Hopps et al. evaluated 78 men with AZF deletions, including three with AZFa deletion, 11 with AZFb, 42 with AZFc, 16 with AZFb + c and 6 with Yq (AZFa + b + c) deletions (Hopps et al., 2003). Within this group, all men with AZFa, AZFb, AZFb + c, and Yq deletions were found to be completely azoospermic. Men with isolated AZFc deletions had more favorable clinical outcomes, with sperm found in 75% (9/12) after TESE and 45% (9/20) on biopsy with an overall sperm extraction rate of 56.3% (Hopps et al., 2003). Further follow up of this cohort confirmed that all microdissection TESE performed for patients with AZFa, AZFb, AZFb + c, and Yq deletions failed to obtain sperm while sperm extraction was successful in 15/21 (71.4%) men with isolated AZFc YCM (Stahl et al., 2010). This rate of sperm extraction for men with isolated AZFc YCM was comparable to the 48.8% retrieval rate for 385 idiopathic azoospermic men without YCM who underwent TESE during the same time period (Stahl et al., 2010). In summation, AZFa and AZFb subregion YCM have a uniformly dismal prognosis for sperm retrieval and future fertility. Conversely, isolated AZFc YCM may present with either severe oligospermia or azoospermia, but the majority of these men will have sperm present at the time of TESE, which may be utilized for intracytoplasmic sperm injection (ICSI) or in vitro fertilization (IVF). It is important to note that while spermatogenesis is impaired for men with isolated AZFc microdeletions that retrieved sperm are capable for fertilization and producing term pregnancies with favorable fertilization rates when compared to patients with non-obstructive azoospermia without gene deletions (Mulhall et al., 1997).

Other Y Chromosome Microdeletions: USP9Y and Gr/Gr Mutations

In addition to deletions, a number of genetic polymorphisms have been investigated to determine their role in male factor infertility. These include the USP9Y gene within the AZFa region of the Y chromosome, which has been associated with mild to severe oligospermia or azoospermia and subsequent male infertility in several studies (Sun et al., 1999; Ferlin et al., 2007). This USP9Y gene provides instruction for a protein called ubiquitin specific protease 9 (USP9), resulting in either cessation of production of the USP9 protein or in an abnormally short and nonfunctional version of the protein and resultant spermatogenic failure and Y chromosome infertility. While initial reports considered this mutation to be a cause of male factor infertility, more recent case reports have demonstrated spermatogenesis and normal sperm counts in men with USP9Y mutations (Luddi et al., 2009), and as such the previously described azoospermia and oligoasthenospermia cannot be completely due to the deletion of this gene and additional genetic or nongenetic factors may be contributing toward this clinical presentation. These reports are in line with studies reporting that the USP9Y serves to fine tune human spermatogenesis by improving the efficiency of sperm production (Krausz et al., 2006) rather than having an intrinsic function.

Similarly, the gr/gr mutation, a partial deletion within the AZFc region has also been identified as a potential risk factor for male factor infertility. Within one cohort of Italian men presenting with infertility, these partial AZFc deletions were associated with 5.3%

Table 1 AZF microdeletions

Mutation	Frequency	Genes affected	Prognosis
AZFa	Rare	DDX3Y and DBY or USP9Y	Sertoli only syndrome: no sperm
AZFb	Rare	RBMY1 PRY	No sperm
AZFc	10% of men with nonobstructive azoospermia, 1:4000 overall (Hotaling, 2014)	DAZ, gr/gr	Rarely sperm in ejaculate, 71.4% chance of finding sperm on mTESE. (Stahl et al., 2010)

of patients presenting with oligo or azoospermia while only 0.5% of fertile controls (Giachini et al., 2005). Conversely, some authors have failed to find statistically significant differences in gr/gr mutations between infertile patients and a fertile control group, and have postulated that gr/gr mutations represent a harmless polymorphism (Ravel et al., 2006). To address the discrepant findings in these studies, one meta-analysis found that gr/gr mutations (OR 1.81, 1.46–2.24 95% CI, $p < 0.01$) and a single MTHFR 677C->T polymorphism (OR 1.39, 1.15–2.69 95% CI, $p < 0.01$) were the only significant polymorphisms associated with male factor infertility (Tuttelmann et al., 2007). While comparisons between different infertility studies may be more difficult due to heterogeneous patient populations and varied clinical approaches, these authors concluded that “genetic studies performed so far emphasize the complexity of male infertility as a presumably polygenetic trait amended by environmental, lifestyle or occupational factors.” (Tuttelmann et al., 2007).

Implications for Fertility

Overall, 11% of men presenting to infertility clinics suffer from unexplained oligo- or azoospermia (Qureshi et al., 1996). Clinical management approaches for YCM and the decision to screen for YCM are highly clinician dependent. Because of the association of YCM with infertility, most abnormalities result de novo with new mutations on the Y chromosome within men with no family history of infertility. Men with a YCM who are able to father children with the assistance of ICSI or IVF should be counseled that this abnormality is passed on to male offspring. As daughters do not inherit a Y chromosome, they are not affected. The rates of YCM vary by population and by presenting symptoms. In one large prospective cohort of 3073 Italian men presenting to infertility clinic, a total of 99 men (3.2%) were identified with YCM (Ferlin et al., 2007). Patients who presented with nonobstructive azoospermia (52 of 625 men, 8.3%) were more likely to have a YCM than men presenting with severe oligospermia (as defined as a sperm concentration <5 million/mL, 47 of 1372 men, 3.4%). Within this cohort, only 2 men of the 99 identified with a YCM were found to have >2 million sperm/mL (Ferlin et al., 2007). This concentration thus may provide a reasonable cutoff for clinicians to consider further testing for YCM. In a similar study of American men presenting with sperm concentrations <5 million/mL, YCM were found in 149 of 1591 overall patients (9.4%), and 10.4% of azoospermic men and 10.1% of men with severe oligospermia (>0–1 million/mL) were found to have YCM within this cohort (Stahl et al., 2010). Given that there have been no reported cases of successful sperm retrieval in men with AZFa or AZFb region deletions, one must thoroughly discuss the reproductive prognostication. Donor sperm or adoption should be discussed as biological children are not possible by current reproductive techniques.

Summary

The discovery of YCMs and their contribution toward male factor infertility represent a breakthrough in the understanding of the genetic basis for spermatogenesis, but many questions still need to be answered. While it is clear that the AZFa and AZFb subregions contain critical information for normal fertility, their exact role remains unclear and further investigation is needed to determine the contributions of single gene deletions and polymorphisms toward spermatogenesis. Additionally, many researchers are working to improve the efficiency and accuracy of YCM diagnosis. Clinically, the ultimate goal is to provide a therapeutic intervention for men with AZFa and AZFb deletions to produce viable sperm; however, that remains an unrealized goal at this time. Hopefully understanding YCMs and their contribution toward the multifactorial etiology of male infertility will provide a window of knowledge that is critical toward driving the next generation of reproductive technology.

Translocations and Male Infertility

Bobby B Najari and Joseph P Alukal, New York University School of Medicine, New York, NY, United States

Introduction

Genetic alterations can negatively impact male reproductive function in a number of ways. The hypothalamic-pituitary-gonadal axis can be negatively impacted by various chromosomal abnormalities (O'Flynn et al., 2010). Men with decreased sperm concentration are more likely to have chromosomal rearrangements (Clementini et al., 2005). In addition to impacting the quantity of sperm, chromosomal alterations can result in abnormal chromosomal segregation during meiosis, which can result in higher rates of sperm aneuploidy (Piomboni et al., 2014). Understanding chromosomal alterations and their impact on male fertility is important for all reproductive healthcare providers.

Chromosomal translocations are structural abnormalities of the chromosomes that are present in infertile men at a rate of 8.5 times the general population (Antonelli et al., 2000). There are two types of translocations, reciprocal and Robertsonian. Robertsonian translocations involve chromosomes in which the centromere is near the end of the chromosome. Reciprocal translocations are exchanges of genetic material between nonhomologous chromosomes. 46,XX male syndrome is often a result of a translocation of the SRY gene from the Y chromosome onto the paired (although not homologous) X chromosome. All of these chromosomal abnormalities have implications on both the reproductive potential of men who carry them, as well as the health of their future offspring.

Robertsonian Translocations

Robertsonian translocations occur between two acrocentric chromosomes, which are chromosomes in which the centromere is close to one end of the chromosome, resulting in a small (*p* for *petit*) length of genetic material beyond the centromere. There are six acrocentric chromosomes in the human genome: 13, 14, 15, 21, 22, and the Y chromosome. A Robertsonian event usually results in a genetic complement of 45 chromosomes due to the fusion of two long (*q*) chromosome arms and the loss of the corresponding two short arms.

In a retrospective review of 333 infertile men, 10 (3%) had Robertsonian translocations (Antonelli et al., 2000). Nine of these involved chromosome 13, and eight involved chromosome 14. Only 2 men of these 10 men had sperm concentrations greater than 20 million/mL, and 3 had concentrations below 5 million/mL, although no men had azoospermia. While all men had adequate percentages of sperm with normal morphology, only one man had sperm motility of at least 50%.

In another retrospective review of 2078 men undergoing IVF/ICSI, 11 (0.5%) had Robertsonian translocations (Clementini et al., 2005). The prevalence of these genetic alterations in the 1559 men with normal sperm concentrations was 0.3%, whereas 1.4% of the 514 men with sperm concentrations <20 million/mL had Robertsonian translocations. Unfortunately, motility was not commented on in this study, but its findings support the notion that this chromosomal abnormality is associated with diminished sperm production.

A more recent study compared 35 men with Robertsonian translocations to 57 men with normal karyotypes and partners with tubal factor female infertility (Pastuszek et al., 2015). While 71.9% of the men with a normal karyotype had sperm concentrations >15 million/mL, only 25.7% of the men with Robertsonian translocations had a normal sperm concentration. Furthermore, while men with a normal karyotype had an average of 40% progressive sperm motility, men with Robertsonian translocations only had 22% progressive motility.

While Robertsonian translocations can be associated with abnormal semen analysis parameters, patients are more concerned with birth rates. In a study of 367 couples with at least 2 miscarriages, Robertsonian translocations were found in 6 couples (1.6%), 4 of which were in the male partner (Kochhar and Ghosh, 2013). Four (67%) of these couples subsequently gave birth, with the remaining two couples having yet another miscarriage. Karyotypes of all six couples revealed two instances of transmission of the Robertsonian translocation: one resulting in a live birth, the other the product of a miscarriage. In a recent report of 2282 infertile men presenting to an andrology clinic in China, 6 (0.3%) had Robertsonian translocations (Guo et al., 2016). Interestingly, only one of these patients had a decreased sperm concentration, which may be relevant to the relatively high live birth rate of 83%.

Robertsonian translocations are associated with abnormal semen analysis profiles. While there are relatively few reports of this condition, it appears to be more common in men with low sperm concentration and low sperm morphology. It is less often associated with azoospermia. Fortunately, live birth rates in men presenting to reproductive medical clinics appear to be within normal ranges.

Reciprocal Translocations

Reciprocal translocations are a transfer of genetic material between homologous chromosomes. These are most commonly balanced exchanges, such that no genetic material is lost and individuals are phenotypically normal. While reciprocal translocations are the

most common structural chromosome abnormality in the general population (0.2% of newborns), infertile men are even more likely to have this abnormality (0.6%) (Mau-Holzmann, 2005). Patients with reciprocal translocation may have a normal phenotype, but this chromosomal abnormality can result in abnormal meiosis. The resulting sperm are more likely to have aneuploidy, which can manifest with recurrent pregnancy loss (Godo et al., 2013).

In a retrospective study of 333 infertile men from 2000, 6 (1.8%) had a reciprocal translocation. Only one of these men had a normal semen analysis. Four men had a sperm concentration less than 1 million/mL. All four men with severely low sperm concentrations also had 0% motility and 0% normal morphology.

In another retrospective review of 2078 men undergoing IVF/ICSI, 15 (0.72%) had reciprocal translocations. The frequency of reciprocal translocations increased as sperm concentration decreased. Whereas 7 (0.45%) of the 1559 men with normal sperm concentrations has a reciprocal translocation, 5 (1.69%) of the 295 men with mild oligospermia (5–20 million/mL), and 3 (2.1%) of the men with severe oligospermia had this chromosomal abnormality.

A more recent study compared 49 men with reciprocal translocations to 57 men with normal karyotypes and partners with tubal factor female infertility (Pastuszek et al., 2015). In contrast to the previous studies, the two groups did not differ in terms of sperm concentration or motility. This study may not have been powered to detect a significant difference in semen analysis parameters between these two groups.

In a study of 367 couples with at least two miscarriages, reciprocal translocations were found in 47 couples (12.8%), 16 of which involved the male partner. The subsequent live birth rate for these male carriers of reciprocal translocations was 61.5%. Of the 14 subsequent miscarriages, 4 (28.5%) were either trisomic or had unreciprocal translocations.

46,XX Male Disorder of Male Development

Patients with XX male syndrome have a 46,XX karyotype, and the disease has an estimated incidence of 1/20,000 male births (Abusheikha et al., 2001). However, the prevalence of this syndrome in men with azoospermia is 0.9% (Mau-Holzmann, 2005). Many patients are phenotypically normal men except for azoospermia, though 33% have gynecomastia, and 10% have hypospadias or ambiguous genitalia (Schweikert et al., 1982).

The most common mechanism for this syndrome is a translocation of the sex-determining region Y (SRY) gene, which encodes testis determining factor (TDF), from Yp to Xq (Page et al., 1987). These areas are known to be highly homologous (Van der Auwera et al., 1992). The gonads (testes) that develop due to the presence of SRY thus produce testosterone, which is why these patients can be phenotypically normal men. While the SRY gene is transferred to the X chromosome, the azoospermic factor region (AZF) and other genes required for normal spermatogenesis remain on the Y chromosome and are lost, explaining these patients' azoospermia.

Approximately 15% of men with 46,XX male syndrome are negative for the SRY gene (Anik et al., 2013). These individuals are more often undermasculinized and have ambiguous genitalia, and are diagnosed earlier than 46,XX SRY positive men. The male phenotype of 46,XX SRY negative individuals is likely due to mutations in autosomal or X-linked genes downstream from testis determining factor, such as SOX9 or DAX1 (Li et al., 2014). For example, multiple copies of the SOX9 gene can result in a 46,XX SRY negative male presentation (Cox et al., 2011).

The reproductive counseling of 46,XX male patients can be emotionally challenging. The potential for genetically-related offspring is nil. Due to the lack of a Y chromosome, and the relevant genes for spermatogenesis, attempts at testicular sperm extraction would be unsuccessful. This information is important to the patient from a prognostic standpoint, obviously, and reiterates the importance of a complete genetic evaluation including karyotype and Y-chromosome microdeletion in the patient presenting with non-obstructive azoospermia.

Conclusion

A variety of chromosomal abnormalities are relevant to the evaluation and treatment of male infertility. Translocations are one particular subset of chromosomal abnormalities that can be identified on karyotype. Both Robertsonian and reciprocal translocations can be associated with impaired semen analysis parameters. Reciprocal translocations are associated with a lower subsequent live birth rate, due to higher rates of sperm aneuploidy. 46,XX male patients can present as phenotypic males, but lack the potential for spermatogenesis.

Identified Epigenetic Effects

Biren V Patel and James M Hotaling, University of Utah, Salt Lake City, Utah, United States

Introduction to Epigenetics

Modern civilization is advancing at breakneck speed. For most of human history, the average life experience and accumulated wisdom changed little from generation to generation. But over the last half century – every decade, there have been fundamental changes to how we live and what we know. Biology has been at the forefront. One of the most important discoveries is DNA, the basic set of instructions for life. The discovery of its structure was heralded as a monumental leap in science. It is a basic language of only four letters – A (Adenine), G (Guanine), C (Cytosine) and T (Thymine) (Pray, 2008). The order of the four letters tells its message. It is heritable, passed down from generation to generation, only changed by mutation in the short run and evolution in the long run (Riggs et al., 1996).

Genetics and genomics, the study of DNA and its structure, are still in their infancy and marching forward. Newer technologies such as genetic engineering have exciting health possibilities. But scientists have also discovered a new field – epigenetics – which may be equally as important. The literal meaning of the prefix “*epi*” is “in addition to” in Greek (Casadesus and Low, 2006). In layman’s terms, epigenetics refers to all the heritable modifications of DNA without changing the sequence.

Review of Epigenetic Mechanisms

Epigenetic processes are those that alter the expression of DNA; they can also be inherited from parents. One can think of three sets signals which accomplish this goal: the epigenator, the initiator and the maintainer (Berger et al., 2009). The epigenator is the inciting event and it generally comes from the environment or diet but can also be a toxin or a secondary messenger molecule. The initiator then takes this event and transmits the signal to the specific location in the genome. The maintainer is the protein or set of proteins which sustain the appropriate DNA structure for future generations (Fig. 1).

Textbooks might slightly differ on the definitions of epigenetic mechanisms but they can be broken into three broad categories based on whether they effect DNA, histones or RNA. The most robustly studied epigenetic modification is DNA methylation. This is

Fig. 1 The Epigenetic Pathway.

Fig. 2 Histone Epigenetics.

the process of adding a methyl group to a DNA base, usually Cytosine (to form 5-methylcytosine). In some rare instances, Adenine can also be methylated (Zemach et al., 2010). This modification is conducted by a set of proteins called DNA methyltransferases. Expression of DNA is generally silenced by methylation as the normal transcription machinery is unable to accurately carry out its function. The conformational change induced by the methylation alters the structure of DNA enough to prevent binding to otherwise available sites.

Histones, dimers or four proteins H2A, H2B, H3 and H4, form an octameric structure around which DNA wraps so that it may be packaged more densely in the nucleus. Histones are the scaffolding proteins of DNA and they can be epigenetically modified via methylation, acetylation, phosphorylation, ubiquitination or sumoylation. These modifications typically occur in the protruding tails which are more accessible to cell signals. Unlike DNA methylation which generally decreases the rate of transcription, histone modifications can either increase or decrease transcription.

Histone methylation and acetylation are carried out by histone methyltransferases and acetyltransferases, respectively. They typically occur on basic amino acids such as arginine, lysine and histidine (Greer and Shi, 2012; Lee and Workman, 2007). These modifications induce conformational change in DNA packing allowing or inhibiting access for transcription machinery. Histone phosphorylation occurs on serine, threonine or tyrosine amino acids and was originally discovered as part of the DNA repair pathway. Recently, it has been shown to have a crucial epigenetic component, interacting with other histone modifications to alter expression of DNA (Banarjee and Chakravarti, 2011). Ubiquitination and sumoylation are often grouped together but are unrelated. Ubiquitination involves the addition of ubiquitin, a small protein discovered several decades ago in the cell degradation pathway. SUMO stands for small ubiquitin-like modifier and is a catch-all category for small regulatory proteins which may act as epigenetic maintainers (Cao and Yan, 2012; Nathan et al., 2006) (Fig. 2). Compared to other epigenetic mechanisms, relatively little is known about ubiquitination and sumoylation.

RNA transcripts are also involved in epigenetic pathways. Messenger RNA (mRNA) can be alternatively spliced or modified (methylated) and descendants of the cells will have inherited these alterations. There are also non-coding RNA fragments (sRNAs) which have been shown to modulate gene expression (Howden et al., 2013). MicroRNAs (miRNAs) are another family of RNA molecules and they are even smaller than sRNA. Over 2000 have been discovered and each miRNA can potentially target up to 200 different mRNA transcripts for destruction (Knopik et al., 2012).

Clinical Applications of Epigenetics

Diet

An important epigenator is obesity which is approaching pandemic levels and affecting nearly two billion people worldwide (Philibert et al., 2012). It is well known that obesity leads to diabetes mellitus, cardiovascular disorders and endocrine dysfunction. These conditions directly contribute to male infertility. In a cross-sectional Australian study of 225 men, obesity was associated with decreased total sperm count (Kim et al., 2010). Body mass index (BMI) was seen to have a negative correlation with sperm concentration, motility and morphology in a prospective multicenter North American study (Salas-Huetos et al., 2017). The odds ratio of subfecundity (time to pregnancy) was increased to 1.18 (overweight) and 1.53 (obese) in a large Danish prospective birth cohort study of over 47,000 individuals (Craig et al., 2017).

Table 1 Summary of Systemic Reviews of Observational Studies (Salas-Huetos et al., 2017)

Summary of Findings	
Diet	Overall association on sperm parameters
Omega-3 fatty acids	Positive
Antioxidants	
Vitamin E	
Vitamin C	
β -carotene	
Selenium	
Zinc	
Cryptoxanthin	
Lycopene	
Vitamins	
Vitamin D	
Folate	
Saturated fatty acids	Negative
<i>trans</i> -Fatty acids	
Seafood	Positive
Fish	
Shellfish	
Poultry	
Cereals	
Vegetables	
Fruits	
Low-fat dairy	
Skimmed milk	
Processed meats	Negative
Soy foods	
Potatoes	
Full-fat dairy products	
Coffee	
Alcohol	
Sugar-sweetened beverages	
Sweets	

Obesity affects spermatogenesis, embryogenesis and offspring health via its epigenetic effects. Excess adipose tissue induces changes in DNA methylation and RNA content. Paternal obesity was found to modulate sperm microRNA and germ cell methylation status in the offspring of mice with diet-induced obesity (Fullston et al., 2013). This was a novel study where founder mice (F0 generation) were fed either a high-fat diet or a control diet for a period of 10 weeks. The F0 experimental mice were allowed to become obese without becoming diabetic and their descendants showed obesity and insulin resistance for two generations. A total of 414 different mRNAs and 11 microRNAs were altered in their descendants. Global methylation was also decreased 25% in their germ cells relative to the descendants from control diet mice.

In humans, pre-conception obesity has been shown to affect methylation patterns in future generations. Analysis of 79 newborn umbilical cord leukocytes showed hypomethylation at the Insulin-like Growth Factor 2 (IGF2) gene-associated regions in newborns with obese fathers (Greer and Shi, 2012). This particular gene was selected because in humans, it is normally paternally imprinted, that is only the copy from the father is expressed. Hypomethylation in these regions not only alters expression of a vital gene but it is associated with increased risks of Wilm's tumor, colorectal cancer and ovarian cancer. The mechanism of action is unknown. This study, like the previously described mouse study, demonstrates the impact of paternal obesity on offspring health.

Vitamins and nutrients also play a role in proper epigenetic programming. A recent systematic review of human observational studies showed that males adhering to a healthy diet could improve semen quality and fecundability (Riggs et al., 1996). A total of 1944 articles were identified and 35 were found to be relevant for the study. Only cross-sectional, case-control, prospective and retrospective studies were included. Diets rich in omega-3 fatty acids, anti-oxidants, vitamins and low in saturated and *trans*-fatty acids were found to be correlated with high quality semen parameters (see Tables 1 and 2). The quality of the sperm is directly related to healthy epigenetic programming.

Environment

Smoking causes abnormal DNA methylation patterns (Howden et al., 2013). A recent study comparing 51 smokers with 57 non-smokers showed that smoking was associated with significant biochemical changes in sperm DNA methylation. Many other studies have shown similar results. 37% of European reproductive age men are smokers, one of the highest rates of tobacco use in the world. A systematic review of 5865 men showed that the toxins from smoking are associated with reduced sperm count and motility

Table 2 Selected Observational Studies Investigating Nutrition and Sperm Quality

<i>Selected Large Association Studies on Nutrition and Sperm Quality</i>				
<i>Study</i>	<i>N</i>	<i>Design</i>	<i>Measured Outcomes</i>	<i>Conclusion</i>
Eslamian et al., 2012	169 normozoospermic controls; 72 asthenozoospermic men	Case-control; Food Frequency Questionnaire	Sperm parameters (volume, motility, morphology and concentration); hormone levels (FSH, LH, Testosterone and Prolactin)	Risk of asthenozoospermia was highest in upper third of processed meat intake; Lowest risk of asthenozoospermia in upper third fruit, vegetables, dark green vegetables, skim milk, poultry and sea food intake.
Minguez-Alarcon et al., 2012	215 healthy men	Cross –sectional; Food Frequency Questionnaire	Sperm parameters (volume, motility, morphology and concentration)	Positive association between increased intake of antioxidants cryptoxanthin, vitamin C, lycopene and β -carotene and total motile sperm count. The semen volume also increased with higher intakes of vitamin C.
Jensen et al., 2013	701 healthy men	Cross - sectional; Food Frequency Questionnaire	Sperm parameters (volume, motility, morphology and concentration)	Lower sperm concentration and total sperm count were associated with high intake of saturated fat in a dose-dependent manner.
Afeiche et al., 2014	155 men attending an infertility clinic	Cross – sectional; Food Frequency Questionnaire	Sperm parameters (volume, motility, morphology and concentration)	Low-fat dairy intake was associated with higher sperm concentration and progressive motility. Cheese intake was associated with lower sperm concentration among past or current smokers.

(Zheng et al., 2017). Toxins from smoking can directly damage sperm DNA, causing increased oxidative stress and increase pro-inflammatory cytokines. These changes are suspected to alter the epigenetic patterns in smokers. Smoking has been associated with altered expression of microRNA (Berger et al., 2009), altered histone modifications (Lim et al., 2005) and changes in phosphorylation (Xia et al., 2008).

Excessive alcohol use has numerous detrimental impacts on male reproduction. Superficially, it causes decreased penile tumescence and ejaculatory capability. Studies have assessed the effect of alcohol directly on spermatozoa in culture at levels comparable to what spermatozoa would be exposed to with social, moderate and heavy drinking (Casadesus and Low, 2006). Rising alcohol concentration was associated with significant decreases in sperm motility and morphology. Chronic alcohol intake has been shown to alter DNA methylation patterns (Wagner et al., 2007). In this study, over 485,000 CpG residues were assessed. These areas are regions of DNA with cytosine nucleotides adjacent to guanine nucleotides, by far the most common location for methylation. Six months of alcohol use was shown to cause widespread alterations in DNA methylation patterns. Alcohol has also been associated with abnormal histone acetylation (Ghezzi et al., 2013).

Ionizing radiation (IR) is another common environmental concern as it may cause widespread genomic instability (Lee and Workman, 2007). Humans are constantly being bombarded with radiation from nature (cosmic rays) and from man-made devices (medical imaging). Many cancers have been linked with radiation including thyroid, leukemia, lymphoma, breast and bladder. The main mechanisms of damage are from single and double stranded helical breaks, base alterations and cross links. These changes not only could be passed on to future generations but the damaged DNA itself can induce further epigenetic changes.

DNA methylation is altered, usually hypomethylated, in response to DNA damage. These changes in somatic cells have been seen to last decades. In germ lines, the aberrant changes are transferred to the next generation. Histones also play a large role in regulating access to damaged DNA. The phosphorylation of histone H2A is one of the most extensively studied modifications in regulating the reaction to double stranded DNA breaks. The phosphorylation of H2A allows unwinding of the histone-DNA complex, presumably to allow repair machinery to enter and in response to IR, the level of phosphorylation increases. There are also global changes in histone methylation and acetylation from IR. Small RNA molecules are also affected by IR-induced stress. Altered expression patterns of mRNA and miRNA have been seen in exposed males as well as their unexposed offspring (Eslamian et al., 2012).

Pesticides also play a significant role in epigenetic perturbation of the male epigenome. Their long-term somatic and male reproductive health implications had been largely unknown until recently. Pesticides are a heterogeneous category of molecules and can

Table 3 Summary of Studies Investigating Pesticides with Semen Quality

Summary of Studies Investigating Pesticides with Semen Quality			
	Author	n	Results
Organochlorines	Aneck-Hahn et al., 2007	311	DDE concentrations associated with decreased sperm concentration; DDE and DDT concentrations associated with decreased motility.
	Messaros et al., 2009	335	High total DDT-DDE exposure had higher odds ratio of low sperm concentration, low motility and poor morphology.
Organophosphates	Perry et al., 2011	152	Farmers with occupational pesticide exposure had higher risks for lower semen volume, lower concentration, higher abnormal morphology and decreased sperm motility.
	Perry et al., 2011	189	Men with abnormal sperm concentration and motility had higher levels of urinary DMP.
Pyrethroids	Ji et al., 2011.	240	Association between 3-PBA urine levels and decreased sperm concentration
	Xia et al., 2008	376	Higher urine 3-PBA concentration had higher odds of poorer sperm concentration

DDE: dichlorodiphenyldichloroethylene
DDT: dichlorodiphenyltrichloroethane
DMP: dimethylphosphate
3-PBA: 3-phenoxybenzoic acid

be grouped into categories: pyrethroids, organochlorines and organophosphates. One systematic review demonstrated that a number of pesticides negatively impacted sperm quality (Lee and Workman, 2007) (see Table 3). The most commonly reported finding with various pesticide classes was decreased sperm concentration.

The noxious effect of the pesticides on sperm quality also impact the epigenome (Filkowski et al., 2010). Organochlorines have been shown to alter global DNA methylation. In one study, low dose exposure to persistent organochlorines resulted in global hypomethylation in 86 otherwise healthy Koreans (Kim et al., 2010). Exposure to organochlorines and organophosphates has been shown to alter methylation patterns in rat brains and liver, respectively. Histone acetylation and miRNA expression changes in the presence of pesticides have also been documented (Collota et al., 2012).

Other environmental pollutants include bisphenol A (BPA) exposure, which has become a widespread problem. Many studies have demonstrated deleterious effects of BPA on male reproduction and epigenetic machinery (Zheng et al., 2017). Air pollutants (particulate matter, black carbon, benzene) and metals (arsenic, nickel, chromium, mercury) have also been examined as potential epigenators (Baccarelli and Bollati, 2009). Metals are also linked with oxidative stress which is known to cause direct DNA damage and trigger an inflammatory state. The cell responds to these triggers by altering access to DNA, blocking access to healthy regions and opening up damaged ones for repair. Reactive oxygen species directly damage key proteins in the epigenetic enzymatic steps (methyltransferases, acetyltransferases) rendering the proteins ineffective.

Arsenic toxicity has been shown to change miRNA expression (Marsit et al., 2006). Nickel is hypothesized to exert its mechanism by displacing magnesium, which normally plays a pivotal role in DNA stabilizing interactions. Nickel also enhances DNA and histone methylation while reducing histone acetylation. Likewise, chromium reduces histone phosphorylation, methylation and acetylation. In-utero mercury exposure is known to cause significant learning and developmental disorders (Baccarelli and Bollati, 2009).

Air pollution has also been associated with global epigenetic alterations. The three most common measures of air pollution include particulate matter, black carbon and benzene. Particulate matter is the sum of all small solid and liquid particles in the air. Black carbon is a byproduct of vehicle exhaust. Benzene is a pollutant from crude oil most commonly encountered at gas stations. These pollutants all cause widespread DNA hypomethylation.

Medications

One of the most exciting areas in biopharma is using small molecules to induce epigenetic changes. This has great potential to improve health outcomes for generations of descendants. Epigenetic mechanisms play a key role in many disease states. For example, hypermethylation of estrogen receptors can increase the risk of atherosclerosis. Neurological diseases, such as Rett syndrome, are the result of excessive DNA methylation which cause gene silencing and subsequent developmental delay. Many cancer pathways are influenced by DNA methylation and histone modification patterns which allow the tumorous cell to escape cell cycle check points (Heerboth et al., 2014).

Potential drug target mechanisms include inhibition of methylation and acetylation. There are many drugs in the pipeline. Some already exist. 5-azacytidine is a Cytosine analog which is incorporated into DNA. When DNA methyltransferases come to perform the methylation, an irreversible binding happens between the protein and 5-azacytidine. The drug has a unique structure which prevents dissociation of the enzyme. This complex is now targeted for destruction by the cell. Histone acetyltransferase inhibitors have potential to be used in many cancers and diseases. Curcumin, a naturally occurring HAT inhibitor, has been shown to inhibit cell growth and proliferation. Modified garcinol (extracted from fruit) and anacardiac acid (extracted from cashews) also act as HAT inhibitors and have been shown to induce apoptosis.

Thoughts on Future

The epigenome, representing the cross roads of environmental, lifestyle and inherited protein expression patterns, will likely drive much of the future research in reproductive medicine. This burgeoning field is just beginning to be translated into clinically actionable items. The future of the epigenome may hold the key to not only reproductive health but also the health of future generations.

LH Luteinizing hormone.

MAIS Mild androgen insensitivity syndrome.

PAIS Partial androgen insensitivity syndrome.

T Testosterone.

Genetic Causes of Congenital Hypogonadotropic Hypogonadism

Idiopathic hypogonadotropic hypogonadism is a genetic disease that may be either the result of an isolated impaired secretion of gonadotropins due to lack of hypothalamic GnRH neurons or the consequence of the impaired production of pituitary hormones, but it may also occur as a feature of genetic syndromes resulting in multiorgan impairment. Isolated FSH and LH deficit due to genetic mutations have been also described, although in very rare cases.

Isolated Congenital Hypogonadotropic Hypogonadism

Isolated congenital hypogonadotropic hypogonadism (ICHH) is a rare disorder that is primarily caused by deficient production, secretion, or action of the gonadotropin-releasing hormone (GnRH) due to lack or deficient number of hypothalamic GnRH neurons, with complete absence of GnRH secretion being suggested by the presence of undetectable or narrowly gonadotropin secretion and/or by a pulsatile GnRH/LH secretion, and is clinically characterized by incomplete or absent puberty and infertility. ICHH can present solely as congenital GnRH deficiency (normosmic ICHH) or be associated with deficient sense of smell (anosmia) as in the condition termed Kallmann syndrome (KS), both conditions accounting for 40% and 60% of all ICHH, respectively ([Mitchell et al., 2011](#)).

The hypogonadotropic state is thought to be originated from impaired GnRH neuron migration from their origin in the olfactory placode to the hypothalamus, with anosmia (in KS) being the result of agenesis/dysgenesis of the olfactory bulb ([Balasubramanian et al., 2010](#)). Several mutated genes may affect the fate and migration of GnRH neurons, and therefore, both normosmic ICHH and KS may be monogenic, digenic, or oligogenic disorders.

Mutations in the KAL1 gene (now denoted as ANOS1) were the first characterized genetic defect reported to cause GnRH deficiency. KAL1 is located on Xp22.3 region, consists of 14 exons encompassing 220 kb of genomic DNA and encodes a modular extracellular matrix-associated 680 amino acid glycosylated protein termed anosmin-1. Anosmin-1 immunoreactivity in human embryos has been shown to be present in the olfactory placode as early as embryonic week 4.5 and is thought to be critical to attracting olfactory axons toward the forebrain. In its absence, this trajectory is lost, and GnRH neurons fail to reach the olfactory bulb initially and subsequently the hypothalamus. The incidence of ANOS1 mutation is approximately 10%–14% in familial and 8%–11% in sporadic KS patients ([Balasubramanian et al., 2010](#)).

GnRH neuron migrations may be affected by mutations in other genes/pathways ([Table 1](#)), namely, PROK2 (3p13) and PROKR2 (20p12.3), WDR11 (10q26.12), SEMA3A (7q21.11), NELF (9q34.3), FGFR1 (8p11.2-p11.1), and HS6ST1 (2q14.3). On the other hand, mutations in FGF8 (10q24.3) and CHD7 (8q12.2) may affect the neurogenic niche in the nasal area and craniofacial development. While mutations in ANOS1 and NELF are specific to KS, mutations in PROK2, PROKR2, WDR11, SEMA3A, FGFR1, HS6ST1, FGF8, and CHD7 may lead to both KS and normosmic ICHH ([Boehm et al., 2015](#)).

Postmigratory GnRH neurons are surrounded by a complex neuronal network of afferents, including kisspeptin-producing neurons that are essential for the different aspects of GnRH function, including the tonic feedback control of GnRH and/or

Table 1 List of genes associated with KS or normosmic ICHH

<i>Genes/pathways</i>	<i>Inheritance</i>	<i>Puberty</i>	<i>Reproductive phenotype^a</i>	<i>Nonreproductive phenotype^a</i>	<i>Response to GnRH therapy</i>	<i>Male reversibility</i>
Kal-1	X-linked	Absent/partial	Cryptorchidism, micropenis	Anosmia, unilateral renal agenesis	Variable	ND
FGF8	AD	Absent/partial	Cryptorchidism, micropenis	Cleft lip/palate, skeletal abnormalities, dental agenesis	Positive	ND
FGFR1	AD	Absent/partial	Cryptorchidism, micropenis	Cleft lip/palate, skeletal abnormalities, dental agenesis	Positive	Yes
PROK2	AR/AD	Absent/partial	Cryptorchidism, micropenis	Synkinesia	Positive	ND
PROKR2	AR/AD	Absent/partial	Cryptorchidism, micropenis	Synkinesia	Positive	Yes
CHD7	AD	Absent/partial	Cryptorchidism, micropenis	Hearing loss	Positive	
HS6T1	AD	Absent/partial	Micropenis	Cleft lip/palate	ND	Yes

gonadotropin secretion and that have been demonstrated to undergo a dynamic process of prenatal and postnatal maturation that enables them to establish connections with GnRH neurons early in development (Boehm et al., 2015). Relevantly, inactivating mutations in genes encoding kisspeptin-1 (KISS1) and its receptor (KISS1R) halt pubertal development in humans. Mutations in TAC3 (encoding tachykinin-3) and TACR3 (encoding tachykinin receptor 3) in patients with ICHH have revealed that such members of the tachykinin family play a key role in the control of GnRH neurons. Also peripheral signals that convey information about metabolic status indirectly modulate GnRH neurosecretion, as demonstrated by the reproductive phenotype of patients with inactivating mutations in the genes encoding leptin (LEP) or its receptor (LEPR). Normosmic ICHH due to mutation in GnRH1 or GnRHR genes is very rare (Mitchell et al., 2011). The list of genes associated with normosmic ICHH is displayed in Table 2.

Combined Pituitary Hormone Deficiency

Combined pituitary hormone deficiency (CPHD) is characterized by the impaired growth hormone (GH) production with one or more other pituitary hormones deficit. For the purpose of this article, only those mutations leading to gonadotropin deficiency will be described.

Since the development of the pituitary gland is the result of the interaction between a number of signaling molecules and transcription factors, mutations in early transcription factors such as HESX1, Gli2, SOX3, and LHX3 are associated with complex pituitary phenotypes with extrapituitary manifestations including syndromic hypopituitarism, while mutations in later-acting transcription factors like PROP1 are associated with pituitary specific phenotypes (Table 3) (Giordano, 2016).

Table 2 List of genes associated with normosmic ICHH

<i>Genes/pathways</i>	<i>Inheritance</i>	<i>Puberty</i>	<i>Reproductive phenotype^a</i>	<i>Nonreproductive phenotype</i>	<i>Response to GnRH therapy</i>	<i>Male reversibility</i>
GnRH1	AR	Absent	Micropenis	None	Yes	ND
GnRHR	AR	Absent/incomplete/delayed	Cryptorchidism, micropenis	None	Variable	ND
KISS1	AR	Absent	Cryptorchidism, micropenis	None	ND	ND
KISS1R	AR/AD	Absent	Cryptorchidism, micropenis	None	ND	ND
TAC3	AR	Absent	Cryptorchidism, micropenis	None	ND	Yes
TACR3	AR	Absent	Cryptorchidism, micropenis	None	ND	Yes
LEP	AR	Absent/incomplete		Obesity	ND	ND
LEPR	AR	Absent/incomplete		Obesity	ND	ND

AD, Autosomal dominant; AR, autosomal recessive; ND, not determined.

^aThe described phenotypes are observed in a variable proportion of patients.

Table 3 Genetic causes of combined pituitary hormone deficiency

<i>Gene</i>	<i>Inheritance</i>	<i>Pituitary hormone deficiency</i>	<i>Associated extrapituitary phenotypes</i>
PROP1	AR	FSH, LH, GH, PRL, TSH, ACTH	None
LHX3	AR	FSH, LH, GH, ACTH, TSH, PRL	Sensorineural hearing loss, limited neck rotation
LHX4	AR/AD	FSH, LH, GH, PRL, TSH, ACTH	Cerebellum anomalies
HESX1	AD/AR	GH to variable CPHD	Septooptic dysplasia
GLI2	AD	GH, PRL, TSH, FSH, LH, ACTH	Holoprosencephaly, craniofacial abnormalities, polydactyly
SOX3	X-linked	GH to variable CPHD	Intellectual disability, midline defects, infundibular hypoplasia

AD, Autosomal dominant; AR, autosomal recessive; CPHD, complete pituitary hormone deficiency.

From Giordano, M. (2016). Genetic causes of isolated and combined pituitary hormone deficiency. *Best Practice & Research Clinical Endocrinology & Metabolism* **30**, 679–691.

According to a large case series, the PROP1 mutations represent the most common known genetic cause of CPHD in sporadic (6.7%) and familial cases (48.5%). Two variants, c.301_302delAG and c150delA represent > 90% of the mutated alleles found in the Eastern European cohorts (Giordano, 2016). A recent study suggests that PROP1 is expressed in a progenitor cell that can develop into all anterior lobe cell types and that all hormone-secreting cell types of both the anterior and intermediate lobes are descended from PROP1-expressing progenitors (Davis et al., 2016).

HESX1 mutations at both the homozygous and the heterozygous states have been reported and may be associated with septooptic dysplasia, pituitary aplasia, or ectopic neurohypophysis. LHX3 mutations show very low mutation frequency both in sporadic (0.3%) and familial cases (11%). Homozygous LHX4 mutations are extremely rare and lethal due to severe panhypopituitarism and pulmonary failure, while patients with heterozygous mutations present with variable GH, TSH, ACTH, and gonadotropin deficiencies.

Genetic Syndromes Resulting in Multiorgan Impairment

Hypogonadotropic hypogonadism may be a feature of genetic syndromes resulting in multiple organ anomalies.

PNPLA6 mutations span a phenotypic variety characterized by variable combinations of clinical features including cerebellar ataxia, upper motor neuron involvement manifesting as spasticity and/or brisk reflexes, chorioretinal dystrophy associated with variable degrees of reduced visual function, and hypogonadotropic hypogonadism either in isolation or as part of anterior hypopituitarism. Less frequent features include peripheral neuropathy, impaired cognitive functioning, hair anomalies/scalp alopecia, and short stature. Some of these features can present in distinct clusters such as in Boucher–Neuhäuser syndrome, Gordon Holmes syndrome, Oliver–McFarlane syndrome, and Laurence–Moon syndrome (Table 4). PNPLA6-related disorders are inherited in an autosomal recessive manner; penetrance appears to be complete in individuals with biallelic PNPLA6 pathogenic variants (Synofzik et al., 2014).

NR0B1 is transcription factors expressed in the adrenal gland and reproductive axis during fetal development and in adult life. Mutations in genes encoding this factor are associated with primary adrenal insufficiency in early infancy or childhood, hypogonadotropic hypogonadism at puberty, and impaired spermatogenesis. Late onset form of this conditions presents with progressive or mild adrenal insufficiency and partial hypogonadotropic hypogonadism (HH).

Bardet–Biedl syndrome (BBS) is a rare genetic disorder with severe multiorgan impairment. Four to six primary features are needed for the diagnosis: retinal dystrophy, polydactyly, obesity, genital abnormalities, renal defects, and learning difficulties. Other (secondary) features may include brachydactyly/syndactyly, diabetes mellitus, developmental delay, speech deficit, dental defects, ataxia, olfactory deficit, and congenital heart disease. There are already 21 known BBS genes (BBS1–BBS20 and NPHP1): The mode of inheritance is autosomal recessive, but incomplete penetrance at least for some genes and/or types of mutations has been hypothesized.

CHARGE syndrome is characterized by a multitude of congenital aberrations due to CHD7 mutations. It is diagnosed in 1/10,000 live births. The clinical diagnosis of CHARGE syndrome is based on three out of four major diagnostic criteria (coloboma,

Seattle (WA): University of Washington, Seattle; 1993–2017, [updated 2015 Jun 11].

choanal atresia, ear malformations, and cranial nerve dysfunction). Other features may include choanal atresia, cleft lip/palate, anosmia, genital anomalies, congenital heart defects, tracheoesophageal anomalies, intellectual disability, growth retardation, and hypogonadotropic hypogonadism.

Isolated FSH and LH Deficit

FSH is a dimeric pituitary glycoprotein hormone composed of an α -subunit, encoded by a single gene (CGA) that is common to FSH, LH, hCG, TSH, and a β -subunit. The α -subunit protein is noncovalently joined to the β -subunit to form a biologically active hormone, but it is the β -subunit that confers hormone specificity. The 4.26 kb human FSHB gene is located on chromosome 11p14.1.

Only three males with FSH β mutations have been described in humans to date. The first was homozygous for a Cys82Arg missense mutation, the second demonstrated homozygosity for the Val61X, and the third homozygosity for a Tyr76X nonsense mutation in the FSH beta gene. All had azoospermia with variable testis size (from prepubertal to nearly normal); virilization and pubertal development were normal in two, while one had no evidence of pubertal development. None had gynecomastia or cryptorchidism. All have low/undetectable FSH, unresponsive to GnRH administration, and high LH serum level with exaggerated response to GnRH, while testosterone was low, low normal, or normal. Testicular biopsies were available in two patients and showed a variable degree of seminiferous tubule dysfunction (Siegel et al., 2013).

The LHB subunit gene is located at chromosome 19q13.32. Inactivating mutations of the human luteinizing hormone beta-subunit gene have been described in five men, who had normal genitalia at birth but restrained pubertal development and hypogonadism. Spermatogenesis impairment, ranging from oligozoospermia to azoospermia, may be due to the lack of LH stimulation and low intratesticular testosterone. These patients respond to exogenous hCG administration.

Genetic Causes of Primary (Hypergonadotropic) Hypogonadism

Myotonic Dystrophy

Myotonic dystrophy type 1 (DM1) is a chronic, slowly progressive multisystem disorder caused by expansion of a CTG trinucleotide repeat in the noncoding region of the myotonic dystrophy protein kinase gene (MDPK) that affects skeletal and smooth muscle and the central nervous system, the eye, the heart, and the endocrine system. A Danish study (Ørngreen et al., 2012) on 97 patients with DM1 showed that 17% of the male DM1 patients had increased LH and low levels of plasma testosterone indicating absolute androgen insufficiency, while another 21% had increased LH but normal testosterone levels, indicating relative insufficiency. Numbers of CTG repeats correlated directly with plasma LH and tended to correlate with plasma testosterone levels.

Myotonic dystrophy type 2 (DM2) is caused by a (CCTG) $_n$ expansion in CNBP and is clinically characterized by myotonia (90% of affected individuals) and muscle dysfunction (82%) and less commonly by cardiac conduction defects, posterior subcapsular cataracts, type 2 diabetes mellitus, and testicular failure.

Gonadotropin Resistance

Hormone resistance is caused by inactivating mutations in hormone receptors or by inactivation of the hormone signaling pathways. FSH receptor (FSHR)-inactivating mutations are able to affect the FSH signaling only when they occur in homozygosity. Five men homozygous for the Finnish p.Ala189Val FSHR gene mutation have been identified to date. This 566C $\rightarrow$ T mutation, predicting an alanine to valine substitution, is located in exon 7 of the FSHR gene, in the region encoding the extracellular domain of the receptor molecule, and leads to a marked reduction in ligand binding and signal transduction by the mutated receptor, according to functional testing.

The affected men had normal puberty, small to normal testes volume (4–15 mL), normal testosterone levels, elevated FSH levels, and low inhibin B level, with normal-to-elevated LH levels. Sperm concentrations ranged from <0.1 million/mL to 42 million/mL, and two out of five men fathered two children each (Huhtaniemi and Alevizaki, 2006). This latter finding prompted the investigators to hypothesize that FSH contributes to the quality and quantity of spermatogenesis but is not mandatory for this process per se, as the normal androgen production may be sufficient to maintain spermatogenesis in these patients. This hypothesis, however, is contradicted by the finding of azoospermia in men with FSH β mutations; moreover, findings in female patients with the same FSHR mutation suggest that such mutation could permit some residual receptor activity.

The LH receptor gene mutations will be discussed in the “Genetic Causes of Disorders of Male Sexual Development” section.

Autoimmune Polyendocrine Syndrome Type I

Autoimmune polyendocrine syndrome type I (APS I) is a rare autosomal recessive disorder caused by mutations in a single gene on chromosome 21q22.3, named AIRE, characterized by multiple organ-specific autoimmunity and ectodermal manifestations. The disease usually begins in childhood with candidiasis, followed by hypoparathyroidism and thereafter by adrenal insufficiency (classical triad). Other associated conditions include thyroid autoimmune diseases, chronic active hepatitis, malabsorption,

pernicious anemia, alopecia, and primary hypogonadism, the latter being associated with the presence of autoantibodies against the side-chain cleavage enzyme.

Aromatase Gene Defects

The enzyme aromatase is a member of the cytochrome P450 superfamily and is encoded by the CYP19A1 gene located at chromosome 15q21.2. Both aromatase enzyme and the CYP19A1 gene are expressed in the testis, adipose tissue, skin, and brain and catalyze the conversion of androgens (androstenedione and testosterone) into estrogens (estrone and estradiol).

Aromatase deficiency is an extremely rare disorder in humans. Men with aromatase deficiency usually present after puberty with tall stature due to unfused epiphyses, delayed bone age, eunuchoid skeletal proportions, and bone demineralization; other features may include insulin resistance, obesity, and dyslipidemia. Maternal severe virilization during the early pregnancy may occur. FSH, LH, and testosterone level may be normal high or elevated; the testes volume may be small, normal, or higher than normal (macroorchidism); and spermatogenesis may be normal or impaired. Estrogen replacement may improve the bone, lipid, and glucose metabolism (Bulun, 2014).

Genetic Causes of Disorders of Male Sexual Development

Androgen Receptor Gene Mutations

The androgen receptor (AR) gene is located at Xq11–12 and comprises eight exons; part of exon 1 of the androgen receptor gene encodes for the large activation function domain, exons 2 and 3 form the highly conserved DNA-binding domain (DBD), and exons 4–7 and part of exon 8 encode the ligand-binding domain (LBD). The AR transcriptional activity is inversely proportional to the size of the CAG triplet repeat sequence of the N-terminal domains.

Androgen insensitivity syndromes are disorders resulting from complete (CAIS), partial (PAIS), or mild (MAIS) resistance to androgens in boys or men with normal testis determination. Hundreds of AR mutations have been discovered to date: mutations localized in exons that encode the DBD (2–3) and LBD (4–8) lead to CAIS or PAIS. About 80% of the mutations in DBD and the majority of those in the LBD are missense mutations (Jääskeläinen, 2012).

Patients with CAIS are phenotypically female, presents in infancy with inguinal hernia or labial swelling containing a testis, with blind-ending vagina. Müllerian duct regression, being androgen-independent, is generally normal, and the patients lack a uterus, fallopian tubes, and a cervix. Adult patients show tall stature, high testosterone and LH levels, and normal FSH. Testosterone is peripherally aromatized to estrogens, resulting in serum estradiol concentrations higher than the average levels seen in men but lower than those reported in women. After orchiectomy, serum FSH and LH levels increase further but are only partially suppressed by exogenous estrogen administration, suggesting that a complete resistance to the negative feedback orchestrated by the androgens at the hypothalamus and pituitary level may be present, together with a partial integrity of the negative feedback control effected by the estrogens. Diagnosis may be challenging in infancy: serum AMH level assay may be of help, as its levels are higher in infants with CAIS than in male infants (Hughes et al., 2012). An AR mutation is identified in > 95% of patients with CAIS.

The typical phenotype of PAIS patients is micropenis, severe hypospadias (perineoscrotal), and a bifid scrotum that might contain gonads.

Men with MAIS may be infertile but do not show genital anomalies. In rare cases, high-dose androgen treatment may restore sperm count. The length of AR CAG repeat has been associated with impaired spermatogenesis and seems to correlate with serum testosterone concentration (Jääskeläinen, 2012). MAIS can also manifest as bulbar and spinal muscular atrophy (Kennedy's disease): in addition to the classic neurological features (weakness and wasting of bulbar, facial, and limb muscles), patients have increased testosterone levels associated with gynecomastia and infertility. These patients display a very high AR CAG repeat number (> 38) (Hughes et al., 2012).

5 α -Reductase-2 Deficiency

The 5 α -reductase-2 gene is located on the short arm of chromosome 2 band 23. This gene's enzyme product is expressed in high levels in the epididymides, seminal vesicles, prostate, genital skin, and liver and catalyzes the conversion of testosterone (T) to dihydrotestosterone (DHT). More than 60 mutations of the 5 α -reductase-2 gene have been identified, including those affecting the three largest family ties (New Guinean, Dominican, and Turkish); the condition is inherited as autosomal recessive. Mutations in all fixed exons of the gene have been documented, ranging from point mutations to entire gene deletions: the resulting enzymatic dysfunction ranges from impaired binding of substrate and cofactor to the isozyme, blocked formation of a functional isozyme, or unstable isozyme, with consequent DHT deficiency due to decreased T to DHT conversion (Kang et al., 2014).

At birth, males may display genital ambiguity: The testes and male accessory ducts are present, but since external genitalia development is dependent on intracellular conversion of T to DHT, the urogenital sinus and genital tubercle fail to differentiate normally into the external genitalia, urethra, and prostate, so patients have clitoral-like phallus, bifid scrotum, blind-end vagina, and hypospadias; therefore, most are assigned a female gender. At puberty, the increase in testosterone production leads to virilization (increased muscle mass, penile enlargement, vocal cord enlargement, and scrotal pigmentation), prompting most to transition to the male gender. Adult subjects show sparsity of body hair and the lack of hairline recession but have normal height given

that skeletal maturation is testosterone-dependent. Hormone assay reveals normal-to-elevated T levels and elevated testosterone-to-DHT ratio. A variable degree of spermatogenesis impairment is observed in these patients, but paternity may be achieved through IVF/ICSI (Kang et al., 2014).

CYP17A1 Gene Defects

The CYP17A1 enzyme catalyzes two distinct enzymatic steps in the steroidogenic pathway, the 17 α -hydroxylase and 17,20-lyase. More than 90 mutations in CYP17A1 have been identified to date, including missense and nonsense mutations, insertions, deletions, and splice site variants (Kim et al., 2014). Mutations in the CYP17A1 gene cause a rare form of congenital adrenal hyperplasia (1% of cases) due to complete combined 17 α -hydroxylase/17,20-lyase deficiency or isolated 17,20-lyase deficiency. Mutations affecting the CYP17A1 steroid-binding domain have been found to result in combined 17 α -hydroxylase and 17,20-lyase deficiency, whereas mutations in the redox partner domain may result in isolated 17,20-lyase deficiency. Affected males (46 XY) show under-masculinization of the external genitalia and may present with arterial hypertension and hypokalemia due to accumulation of precursor steroids with mineralocorticoid activity.

LH/hCG Receptor Gene Mutations

The LHR gene is located on chromosome 2p21; inactivation of both alleles through homozygous or compound heterozygous loss-of-function mutations is required to provide a phenotypic effect. Homozygous inactivating LH/hCG receptor (LHCGR) gene mutations in male subjects (46 XY) have been rarely found and usually result in undermasculinization, with female phenotypes (blind-ending vagina and primary amenorrhea). The absence of breast development at the age of puberty represents the clearest phenotypic difference between this condition and complete androgen insensitivity syndrome due to AR inactivating mutation of the androgen receptor, where normal breast development occurs at puberty. Microscopic examination of the removed (inguinal or intraabdominal) gonads showed seminiferous tubules containing normal Sertoli cells, occasional immature germ cells, but no mature Leydig cells. Hormone assay reveals low testosterone level, high LH, and normal FSH. Milder forms of LHR inactivation where the receptor is only partially inactivated result in male phenotypes with micropenis and descended testes. Both phenotypically male and female patients are irresponsive to exogenous hCG administration. Heterozygous mutations leading to constitutive activation of the LHCGR cause gonadotropin-independent precocious puberty in males (Huhtaniemi and Alevizaki, 2006).

Disorders of Sex Determination and Development

Rodrigo L Pagani and Ramy Abou Ghayda, University of Illinois at Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Disorders of Gonadal Differentiation

Klinefelter Syndrome

Klinefelter syndrome is the most common major abnormality of sexual differentiation, and is characterized by males with at least one Y chromosome and at least two X chromosomes. Males with the classic form of Klinefelter syndrome have small, firm testes on physical examination, and histology shows seminiferous tubule degeneration, and hyalinization. Patients with Klinefelter syndrome presents with elevated serum levels of FSH and LH, and low to normal serum levels of testosterone, therefore secondary sexual development may be compromised. Patients have a predisposition for being taller than average and gynecomastia can be noteworthy during puberty. The vast majority of patients are azoospermic, and the presence of sperm suggests 46,XY/47,XXY mosaicism (Diamond and Yu, 2016).

Fertility has been demonstrated to be feasible with the use of microsurgical testicular sperm extraction followed by intracytoplasmic sperm injection with a success rate for sperm retrieval as high as 40%–66% (Ramasamy et al., 2009). Since Klinefelter syndrome patients have a depletion of germ cells at puberty, this has led some expert to advocate for sperm extraction during adolescence for fertility preservation, however this approach remains controversial (Gies et al., 2016). Furthermore, these patients may need androgen supplementation to enhance libido and in some patients, reduction mammoplasty may be required. Surveillance for testicular and breast carcinoma is also warranted.

46,XX Testicular DSD

This condition is characterized by normal testicular development, despite the lack of a normal Y chromosome in subjects who have two X chromosomes. Most patients present later in life with hypergonadotropic hypogonadism, gynecomastia, and azoospermia. Testicular histology shows Sertoli cell only pattern and hyalinization of seminiferous tubules (Vorona et al., 2007).

Two categories of patients with XX testicular DSD have been identified, those who are SRY positive (usually with translocation of SRY to the X chromosome) and rarely have genital abnormalities, and those who are SRY negative and more commonly have genital ambiguity (Ergun-Longmire et al., 2005). Since these patients lack most part of Y chromosome, including genes responsible for spermatogenesis, there has not been a role for assisted reproductive technique in these patients. Similar to Klinefelter syndrome, some patients may benefit from androgen replacement and reduction mammoplasty, since there is an increased risk for breast carcinoma and testis tumor.

Mixed Gonadal Dysgenesis

Mixed gonadal dysgenesis is characterized by a unilateral streak gonad with a contralateral, often dysgenetic, testis. A variant where two dysgenetic testes are present, rather than one dysgenetic testis and a streak gonad, is called partial gonadal dysgenesis. Most of patients have a 45,XO/46,XY karyotype and persistence of Müllerian structures associated with varying degrees of masculinization, including normal male genitalia. In the neonatal period, mixed gonadal dysgenesis is the second most common cause of ambiguous genitalia after congenital adrenal hyperplasia. Histologically, testicular hyalinization, germinal aplasia, and Leydig cell hyperplasia are the most common findings (Johansen et al., 2012). Typically, infertility due to azoospermia exists, however, one case of successful sperm extraction has been reported (Flannigan et al., 2014).

Patients with mixed gonadal dysgenesis have a higher risk of developing a gonadal tumor such as gonadoblastoma and dysgerminoma. They are also at increased risk for Wilms tumor, therefore the appropriate management of these individuals comprises of gender assignment, gonadectomy, and proper screening for Wilms tumor (Diamond and Yu, 2016).

Embryonic Testicular Regression and Bilateral Vanishing Testis

Embryonic testicular regression denotes loss of testicular tissue within the first trimester of pregnancy whereas bilateral vanishing testes syndrome implies individuals in whom male sexual differentiation occurred but loss of testicular tissue took place later in utero. These conditions are exemplified by patients with a 46,XY karyotype and anorchia. Embryonic testicular regression has a wide spectrum of phenotypes ranging from complete female to varying degrees of ambiguous genitalia, while in bilateral vanishing testis a normal male phenotype with micropallus, absent prostate, and empty scrotum is commonly seen. There are no fertility treatment options available, however these patients may benefit from androgen replacement to assure a normal pubertal growth spurt with normal secondary sex characteristics (Diamond and Yu, 2016).

Ovotesticular DSD

Formerly known as true hermaphroditism, ovotesticular DSD occurs in those who encloses both testicular and ovarian tissues, which may take the form of one ovary and one testis or, more commonly, one or two ovotestes. Approximately 60% of the patients with ovotesticular DSD show a 46,XX karyotype, whereas 33% are mosaics 46,XX/46,XY, and 7% have a 46,XY karyotype. Patients are classified according to the type and location of the gonads. Lateral cases (20%) have a testis on one side and an ovary on the other. Bilateral cases (30%) have testicular and ovarian tissue present bilaterally, usually as ovotestes. Unilateral cases (50%) have an ovotestis present on one side and an ovary or testis on the other. The most crucial aspect about dealing with ovotesticular DSD patients is gender assignment. Since most patients present with masculinized ambiguous genitalia, they are usually raised as a male. In these patients, all ovarian and müllerian tissue should be removed (Diamond and Yu, 2016). The ovarian portion of the ovotestis is frequently normal, whereas the testicular portion is typically dysgenetic, therefore only two studies have reported successful pregnancies with sperm harvested from azoospermic men (Younis et al., 2011; Sugawara et al., 2012).

46,XY DSD (Undermasculinized Male)

Leydig Cell Aplasia

This rare autosomal recessive disorder is characterized by normal 46,XY male karyotype with a variety of phenotypes depending on the genetic mutation, with severe forms presenting as normal-appearing female external genitalia, and milder forms with micropenis or hypospadias (Van Batavia and Kolon, 2016). Testes are usually palpable in the inguinal canals or labia. Serum LH levels are elevated and testosterone levels are usually low. This disorder represents a spectrum between absent Leydig cells and Leydig cells with abnormal LH receptor. Incomplete forms of the disorder may also be present in patients with normal male genitalia. Recently, it was reported the first successful sperm retrieval with successful in vitro fertilization that resulted in a live birth (Bakircioglu et al., 2014).

Steroidogenic Acute Regulatory Protein (StAR) Deficiency

Steroidogenesis is the process in which cholesterol is converted into testosterone. The first step is based on the conversion of cholesterol to pregnenolone, mediated by an enzyme known as cholesterol side-chain cleavage (P450_{scc}) enzyme, that when defective result in a condition called congenital lipoid adrenal hyperplasia (Diamond and Yu, 2016).

The steroidogenic acute regulatory protein (StAR) promotes cholesterol transport from the outer to the inner mitochondrial membrane and has been also associated as a cause of congenital lipoid adrenal hyperplasia (Saenger, 1997).

Individuals with this condition are subject to present with severe glucocorticoid deficiency early in life and progressive mineralocorticoid insufficiency resulting in hyponatremia, hyperkalemia, dehydration, acidosis, and collapse. In 46,XY individuals, mutations in StAR typically cause a marked deficiency in testosterone synthesis by fetal Leydig cells so that completely female genitalia is encountered. Testes may be localized in the abdomen, inguinal channel, or in the labia. A blind vaginal pouch is present and müllerian structures have degenerated (Bhangoo et al., 2005). Some patients have mutations that retain partial activity, hence normal pubertal development and adult sexual function may occur, and fertility has been reported (Metherell et al., 2009).

P450 Oxidoreductase (POR) Deficiency

P450 oxidoreductase (POR) plays a central role in electrons transfer from NADPH to P450 enzymes, and its mutation cause a complex steroidogenic spectrum including partial P450_{c17}, aromatase, and 21-hydroxylase deficiencies (Krone et al., 2012). This mutation was originally characterized in patients with Antley-Bixler syndrome, some of whom had ambiguous genitalia and abnormal steroidogenesis. Mildly affected males may present with normal or delayed pubertal development and hypogonadism, nevertheless fertility has not been reported in this group (Idkowiak et al., 2011).

3 β -Hydroxysteroid Dehydrogenase Deficiency

A 3 β -hydroxysteroid dehydrogenase deficiency affects steroidogenesis in both the adrenal glands and testes, usually presenting in newborn boys with small phallus, severe hypospadias, ambiguous genitalia and salt-wasting adrenal insufficiency. Spontaneous pubertal development has been reported but testicular biopsy usually shows spermatogenic arrest or germinal aplasia, although one case of paternity has been documented (Guercio et al., 2015).

21-Hydroxylase Deficiency

Congenital adrenal hyperplasia (CAH) is the most common cause of the 46,XX DSD (masculinized female) and ambiguous genitalia at birth and a deficiency of steroid 21-hydroxylase is responsible for 95% of cases of CAH. Of these patients with 21-hydroxylase deficiency, 75% of patients presents with virilization and aldosterone deficiency, while 25% of patients presents

only with virilization. Plasma levels of progesterone and 17-hydroxyprogesterone are markedly elevated as well as urinary levels of 17-ketosteroids and pregnanetriol (Diamond and Yu, 2016).

In both males and females with aldosterone deficiency, symptoms begin within the first few weeks after birth, with failure to regain birth weight, progressive weight loss, and dehydration. Males with CAH appear phenotypically normal, and those without salt wasting may show sexual and somatic precocity. Therefore, these children have enlargement of the penis accompanied by the appearance of pubic hair, acne, and deepening of the voice.

Men with classic CAH have reduced fertility compared with controls, as well as higher rates of abnormal semen analysis, which is likely due to the presence of testicular adrenal rest tumors and suppression of the hypothalamic–pituitary–gonadal axis by high systemic levels of androgens (Reisch et al., 2009). One study comparing men with CAH to controls found that fertility rates in the CAH men were approximately half of those seen in the controls (Falhammar et al., 2012). While testicular adrenal rest tumors are considered to be benign, they can cause infertility through compression of the seminiferous tubules leading to obstruction, decreased spermatogenesis, and peritubular fibrosis (Van Batavia and Kolon, 2016).

17 α -Hydroxylase Deficiency

17 α -Hydroxylase catalyzes the conversion of pregnenolone and progesterone to 17 α -hydroxypregnenolone and 17-hydroxyprogesterone respectively. In 46,XY with complete 17 α -hydroxylase deficiency, individuals have a normal external female phenotype with blind-ending vaginal pouch. In 46,XY with partial 17 α -hydroxylase deficiency, a variety of phenotype may be present, including hypospadias, and cryptorchidism. No cases of fertility have been reported (Diamond and Yu, 2016).

17,20-Lyase Deficiency

Differently from complete 17 α -hydroxylase deficiency, complete 17,20-lyase deficiency results in ambiguous genitalia at birth of a 46,XY individual. Diagnosis is suspected in undervirilized males with failure to develop secondary sexual characteristics and elevated gonadotropin levels (Diamond and Yu, 2016).

17 β -Hydroxysteroid Oxidoreductase Deficiency

17 β -Hydroxysteroid oxidoreductase is the last enzyme in the biosynthesis of testosterone and catalyzes the conversion of androstenedione to testosterone, DHEA to androstanedione, and estrone to estradiol. Since most individuals have a normal female phenotype at birth, female gender assignment is commonly made, however as these patients have well-differentiated testes located in the abdomen or inguinal canal, the phallus growth, and secondary male sexual characteristics develop during puberty (Diamond and Yu, 2016). For individuals reared as female, treatment includes gonadectomy and estrogen replacement. For male gender of rearing, treatment includes orchiopexy and external genitalia reconstruction. Infertility due to azoospermia is the rule in these boys.

Complete Androgen Insensitivity Syndrome

Patients with complete androgen insensitivity syndrome (CAIS) are characterized by female-appearing external genitalia with short, blind-ending vagina, absence of müllerian ducts, and bilateral abdominal or inguinal testes in a 46,XY individual. Many patients are diagnosed later in life due to primary amenorrhea or the finding of testes during hernia repair. Testicular development is severely abnormal and the potential for male fertility is extremely low.

As the risk of developing a testicular tumor increases with age, including seminoma or gonadoblastoma, some authors advocate the need for gonadectomy after puberty, mainly because at these ages, the testes start to produce estradiol, which results in the appropriate changes for secondary sexual characteristics (Ahmed et al., 2000). Nevertheless, each patient should receive an individualized approach discussing all the possible scenarios, and at this point in time, all patients support a female gender identity (Hughes et al., 2012).

Partial Androgen Insensitivity Syndrome

The classic phenotype for patients is partial androgen insensitivity syndrome (PAIS) is that of a male with perineoscrotal hypospadias, cryptorchidism, rudimentary wolffian duct structures, and gynecomastia. However, variable phenotypes ranging from external genital ambiguity to male infertility may be found, and management of these patients is individualized according to findings in the phenotype (Diamond and Yu, 2016).

Patients raised as female should undergo gonadectomy and surgical reconstruction of the external genitalia at the time of diagnosis, while patients reared as males require treatment of cryptorchidism, reduction of gynecomastia, and genital reconstruction. Fertility (both spontaneously and with assisted reproduction) is possible in individuals raised as male, whereas in patients raised as female are always infertile (Tordjman et al., 2014).

Mild Androgen Insensitivity Syndrome

Males with mild androgen insensitivity syndrome (MAIS) are usually phenotypically normal or may have a history of mild hypospadias. These patients are often diagnosed during workup for male factor infertility and they usually present with azoospermia or severe oligospermia, and normal to elevated testosterone levels (Hiort and Holterhus, 2003).

5 α -Reductase Deficiency

5 α -reductase is a microsomal enzyme that catalyzes the conversion of testosterone to dihydrotestosterone (DHT), which is the main androgen driving the masculinization of the urogenital sinus and external genitalia. However, DHT does not play a major role in spermatogenesis. Affected patients show ambiguous genitalia with hypospadias and cryptorchidism. Typically, the phallus is quite small, appearing as a normal or enlarged clitoris (Maimoun et al., 2011). At puberty, spontaneous virilization occurs and adult patients report male libido and erections. On endocrine evaluation these individuals have elevated mean plasma testosterone but low DHT levels. Semen analysis is characterized by extremely low volume, increased viscosity, and poor liquefaction, attributed to rudimentary prostate glands, and small seminal vesicles (Katz et al., 1996).

In 2008, one study compared testicular histopathology of boys affected with the disease to boys with isolated bilateral cryptorchidism, and demonstrated that the first group presented with normal germ cell count and Ad spermatogonia, while the latter group had reduced total germ cell counts with poor cell maturation into Ad spermatogonia (Hadziselimovic and Dessouky, 2008). Most of the affected individuals are infertile, although spontaneous proven fertility was reported, as well successful pregnancies following assisted reproductive techniques (Katz et al., 1996; Nordenskjöld and Ivarsson, 1998).

Persistent Müllerian Duct Syndrome

Defects in testicular antimüllerian hormone production as well as defects in antimüllerian hormone receptors lead to persistent müllerian duct syndrome (PMDS), characterized by patients with 46,XY karyotype and normal external genitalia but internal müllerian duct structures. Therefore, they present with unilateral or bilateral undescended testes, bilateral fallopian tubes, uterus, and an upper vagina draining into a prostatic utricle (Diamond and Yu, 2016).

As all patients are phenotypically males, treatment involves orchidopexy and resection of the rudimentary müllerian structures. Azoospermia is common due to cryptorchidism or to damage of testicular blood supply during surgical procedures (Josso et al., 2012).

Congenital Bilateral Absence of the vas Deferens

Gabriella Avellino and Robert D Oates, Boston University School of Medicine, Boston, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Congenital bilateral absence of the vas deferens The clinical condition resulting from an absence of the reproductive ductal structures that transport sperm from the testis to the ejaculate.

Cystic fibrosis transmembrane conductance regulator (CFTR) The protein product of the cystic fibrosis or *CFTR* gene.

Intracytoplasmic sperm injection An advanced reproductive technique where an individual sperm is micro-injected into the cytoplasm of a harvested egg.

Introduction

Congenital bilateral absence of the vas deferens (CBAVD), as a primary disorder, presents as low volume azoospermia and consequent infertility (Harnisch and Oates, 2012). The vasa deferentia constitute the major portion of the male reproductive ductal system and transport sperm from the testis to the ejaculate and are classically not able to be felt upon scrotal examination. CBAVD may be diagnosed as an isolated condition when the male has no recognizable pulmonary or pancreatic symptoms, but will always be present in boys and men with clinically diagnosed cystic fibrosis (CF). Asymptomatic CBAVD and classic CF are often two ends of a spectrum of genetic disease, as described more fully below. Finally, some cases of CBAVD coexist with abnormalities of the urologic tract, specifically unilateral renal agenesis and/or ectopy. CBAVD is found in 1%–2% of infertile men (Hotelling, 2014).

Phenotypic and Semen Analysis Findings in Men With CBAVD

Men with CBAVD have a normal hypothalamic-pituitary–gonadal axis. Libido and testicular function are fine as regards testosterone synthesis and sperm production (spermatogenesis). A brief review of male reproductive embryology is necessary in order to understand the anatomical findings and anomalies in CBAVD. During early embryogenesis and fetal development, each mesonephric duct (left and right) gives rise to two separate derivatives in and around week 7 of gestation. The most superior (anatomically) becomes the ureter and intrarenal collecting system while the most inferior (anatomically) gives rise to the distal two-thirds of the epididymis, the entire vas deferens, the seminal vesicle and the ejaculatory duct. The first portion of the epididymis (the caput—an entanglement of 6–8 efferent ducts) does not derive from the mesonephric duct and connects directly to the rete testis (the first collecting area for newly formed sperm within the testis). Therefore, the caput of the epididymis is always present in CBAVD, the more distal epididymides may be present to a quite variable degree, the vasa are absent by definition, and the seminal vesicles are typically deficient or non-functional.

The seminal vesicles produce the majority of the fluid found in the ejaculate and all of the alkalinity (Centola, 2014). The prostate is unaffected in CBAVD and secretes a small amount of acidic fluid. When the male is unaffected by any abnormalities, the volume and alkalinity of the seminal vesicle fluid overwhelms the small amount of prostatic fluid and so the ejaculate, as a final mixture, is of a “normal” volume and alkaline pH. In CBAVD, however, the seminal fluid consists of just a small amount of prostatic contribution which is acidic, averaging about 0.6 cm³ and pH of 6.5. There is no contribution from the seminal vesicles as they are absent or severely atretic and no sperm as the vasa deferentia are absent. In consequence, a low volume, acidic, azoospermic ejaculate should always raise suspicion of CBAVD, which is confirmed easily upon physical examination: adequately sized testes, at a minimum the caput epididymis is present, the vasa are not able to be palpated (Oates, 2012).

The Genetic Basis of Most Cases of CBAVD: Mutations in *CFTR*

CF is a common autonomic recessive disorder in Caucasians of Northern European descent, found in 1 in 2500–3500 neonates in the United States. Comparatively, it is diagnosed in about 1 in 17,000 African Americans and 1 in 31,000 Asian Americans (Farrell et al., 2017). Over 2000 mutations of the CF gene (also termed *CFTR* for its protein product (Cystic Fibrosis Transmembrane Conductance Regulator; located on the long arm of chromosome 7) have been discovered and annotated (Deignan and Grody, 2016). The most common mutation worldwide is referred to as deltaF508. The *CFTR* gene codes for a transmembrane chloride ion transport channel that helps to balance salt and water concentrations across the cell membrane and keep the secretions of certain epithelial cells in the lungs and pancreas, to name just a couple organs, thin and watery (Cholon and Gentzsch, 2017). When the total pool of cellular *CFTR* is poorly functional, the above mentioned secretions are thick and tenacious and eventually clog and obstruct the tubular system of the airways or the pancreas. During fetal development, *CFTR* also helps to maintain patency and

viability of the developing vas deferens, distal two-thirds of the epididymis and seminal vesicles. Again, when the total cellular functional pool of *CFTR* is reduced, these reproductive ductal structures may not continue their normal development and become atretic and, essentially, disappear.

The genotype–phenotype correlation, when there are defects in *CFTR* quantity or quality, is at the heart of understanding why some males have clinical CF with compromised pulmonary and pancreatic function as well as bilateral absence of the vasa deferentia while other males are perfectly healthy with normal pulmonary and pancreatic function but an absence of the vas deferens bilaterally and infertility. To have any form of recognizable disease, one must inherit a *CFTR* mutation from both parents, that is, a maternal mutation and a paternal mutation. It is the nature of each mutation and the combination of the two that determines the severity of the disease that the patient will exhibit. If a male inherits a *CFTR* mutation from his mother classified as “severe” and one from his father, also classified as “severe,” his total amount of adequately functioning cellular *CFTR* protein will be minimal, if not absent, and his secretions in the respiratory tree and pancreatic excurrent ducts will be viscous and glutinous leading to significant pulmonary and pancreatic disease. His vasa and seminal vesicles will also be absent. His clinical diagnosis will unfortunately be cystic fibrosis. However, if one of the two of those mutations is classified as “mild,” then his cellular *CFTR*, as an aggregate, may have enough quantity and quality to allow the lungs and pancreas to be relatively unaffected (his *CFTR* works “well enough” and his secretions in these organs/systems are thin and fluid “enough”) that he will not express disease until recognized to have CBAVD when presenting for infertility evaluation. The development and maintenance of the reproductive ductal structures is, therefore, the most sensitive indication of *CFTR* mutations in both maternally and paternally inherited alleles (Anguiano et al., 1992). Of course, an individual patient may present anywhere along the spectrum between those two extremes, for example, a male with newly diagnosed CBAVD who has a chronic history of sinusitis or bronchitis. It is the nature of the combination of mutations that determines the phenotype, and by extension the clinical diagnostic term, for the patient. Hence, when a male is diagnosed with CBAVD, it is necessary to obtain CF mutation analysis. Yu et al. provide a comprehensive review of the mutations found in CBAVD, the most common being the 5T allele (25%, considered “mild” in severity) while deltaF508 was the second most common at 17% of alleles (Yu et al., 2012). The combination of deltaF508 and 5T was found in 17% of CBAVD cases. However, the exact frequency and pattern shows skewing based upon inherited ethnicity (Xu et al., 2014). When CF mutation analysis is positive, family screening should also be carried out to inform the patient’s siblings (usually of reproductive age as well) of their risk of harboring one or two *CFTR* mutations. When positive, a new perspective on the etiology and optimal treatment of any heretofore unrecognized CF mutation spectrum coexisting illnesses such as sinusitis, pancreatitis, bronchitis may be realized. Even though the clinical diagnosis of CBAVD is relatively easy and straight forward to make with history and physical examination, the discovery of the underlying genetic basis is important for the above reasons and testing should not be felt unnecessary—it is often a helpful adjunct in cases of CBAVD.

Recently, a new genetic basis, involving *CFTR* function but not the *CFTR* gene, has been identified and will be important to define in selected cases. Patat et al. described four men with *CFTR*-negative CBAVD who were shown to have mutations in *ADGRG2*, which resides on the X chromosome and, therefore, would be maternally transmitted in X-linked fashion (Patat et al., 2016).

The Genetic Basis of a Few Cases of CBAVD: Maldevelopment of the Mesonephric Ducts

Reflecting back on the embryology of the reproductive ductal system, it is obvious that mutations in *CFTR* adversely affect the development of the vasa deferentia long after week 7 of gestation, that is, long after the separation of the two divisions of the mesonephric duct as the kidneys and ureters are normal in *CFTR* mutation directed CBAVD. However, a second broad genetic etiology exists in which there are putative genetic abnormalities which compromise mesonephric duct development at its earliest stages prior to week 7 of gestation. This insult derails normal morphogenesis of both the urinary and reproductive ductal derivatives of the mesonephric ducts. If the end result is bilateral renal agenesis and bilateral vasal agenesis, that individual will not be able to present later in life for an infertility evaluation, for obvious reasons. But if the affront is slightly less severe in totality, then one of the two renal/ureteral derivatives may form, allowing that individual to be healthy with one kidney and present later in adult life with infertility due to CBAVD (1 of the 4 “offspring” of the 2 mesonephric ducts matured and progressed but not the other 3). When *CFTR* mutation analysis is non-informative, it is necessary to perform renal ultrasonography to identify possible unilateral renal agenesis and counsel the patient and his partner accordingly (Schwarzer and Schwarz, 2012). From the data published by McCallum et al., it does not appear that it is likely that unilateral or bilateral renal agenesis will be transmitted to any conceived offspring, although it is possible (McCallum et al., 2001).

Fertility Options for Men With CBAVD

Prior to the advent of advanced reproductive technologies, CBAVD resulted in sterility. However, in the present day, harvested sperm from the epididymis or testis can be used in conjunction with intracytoplasmic sperm injection (ICSI) to achieve biological paternity (Elhanbly et al., 2015; van Wely et al., 2015). ICSI involves oocyte harvest after gonadotropin stimulation and in vitro placement of a single spermatozoan into the interior of the oocyte with a micropipette. Depending upon the philosophy of the practitioners involved, a limited number of embryos generated are transferred a variable number of days later. Since spermatogenesis is not generally an issue, sperm can be surgically retrieved from the most proximal portions of the epididymis (the caput;

		Male <i>CFTR</i> Mutation Status	
		$\Delta F508$	5T
Female <i>CFTR</i> Mutation Status	$\Delta F508$	$\Delta F508 / \Delta F508$ Cystic Fibrosis	$\Delta F508 / 5T$ CBAVD
	+	$\Delta F508 / +$ Carrier (unaffected)	$5T / +$ Carrier (unaffected)

Fig. 1 Punnet square of offspring genotype possibilities in men with *CFTR* mutation directed CBAVD and a female simple heterozygote partner. Embryos shown to be compound heterozygotes for delta F508/delta F508 would not be transferred as they will manifest full-blown CF while embryos that inherit only one mutation (simple heterozygotes; carriers) will be transferred and will become healthy individuals.

fferent ducts) or the testis tissue and will, when injected directly into an egg during ICSI, effect fertilization, embryo development and live birth. Whether the sperm are collected with an open scrotal operation as in microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESE) or testis sperm extraction (TESE) is generally a matter of patient, clinician, and embryologist choice, although there is data suggesting an improved overall outcome with epididymal sperm. What is not possible, is anything short of ICSI as the sperm harvested have limited capacity to carry out normal functions of the sperm in a natural setting. These include progressive motility, acrosome reaction and fertilization of an oocyte by penetrating the zona pellucida and the egg membrane. Once placed into the oocyte cytoplasm during ICSI, they work quite well.

It is necessary to screen the female partner for *CFTR* mutations as well. Approximately 1:25 people of Northern European descent is a carrier of a *CFTR* mutation. A carrier is asymptomatic, has only one *CFTR* allele affected while the other is normal, and is also known as a simple heterozygote. If the male carries two identifiable *CFTR* mutations, as is so often the case, and the female is a simple heterozygote, then 50% of the couple's embryos will have two *CFTR* mutations as shown in Fig. 1. Each embryo will always get one of the two *CFTR* mutation alleles the male possesses and will either get the mutated allele or the normal allele from the female partner. If the female partner is a carrier, then, each embryo can be genetically investigated and only those embryos that were NOT burdened with the maternal *CFTR* mutation transferred (Girardet et al., 2015). In this way, the couple's offspring will be obligate carriers but will not express *CFTR* mutation spectrum disease because they will not have abnormalities in both *CFTR* alleles.

Conclusion

Congenital bilateral absence of the vas deferens (CBAVD) is a clinical condition that typically presents at the time of an evaluation for infertility. An azoospermic semen specimen that is of low volume and an acidic pH is characteristic. Physical examination of the reproductive ductal structures and the testes reveal absence of the vas deferens and, always, at least the caput of the epididymis. Most cases of CBAVD are caused by mutations in both parental cystic fibrosis gene alleles (maternally and paternally inherited CF genes). Some cases are caused by defects in the development of the mesonephric ducts during embryogenesis that may result in associated renal agenesis. No known genetic etiology has yet been elucidated for this subset of CBAVD. Proper genetic screening is mandatory for patient, spouse and appropriate family members. Sperm can be successfully harvested in a number of different ways and used with great efficacy to generate pregnancies and healthy offspring. What was once impossible—pregnancy—is now routine.

Non-CBAVD Extratesticular Ductal Disorders

Alexandra J Berger and Martin N Kathrins, Harvard University, Boston, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Extratesticular ductal disorders have been reported in up to 85% of patients with obstructive azoospermia (Hendry et al., 1983). Obstruction anywhere along the pathway of sperm and semen production and ejaculation can lead to infertility; this includes disruption of the epididymides, vasa deferentia, seminal vesicles or ejaculatory duct (Fig. 1, below). Such patients typically have normal or enlarged testicular volume and physical exam findings which may elucidate the origin of the obstruction (EU 2012). This includes enlarged or indurated epididymis with nodularity, absence of one or both vas deferens or a boggy or tender prostate concerning for prostatitis. The serum follicle stimulating hormone will often be within normal limits.

Epididymal disorders

Epididymal disorders are the most common causes of obstructive azoospermia, occurring in 65% of such cases (Schoysman, 1990; Matsumiya et al., 1994). These obstructions are typically acquired but can also be congenital. Acquired obstruction are most often infectious or inflammatory in etiology, but can also be due to scrotal trauma or prior scrotal surgery.

Epididymitis is a frequent cause of acquired epididymal obstruction. Acute or chronic epididymitis can lead to scarring which chronically occludes the epididymal ducts. The specific etiology of epididymitis is unclear in many patients and may be inflammatory or infectious. Chlamydia trachomatis is the most frequently acquired sexually transmitted infection and is thought to cause both acute and chronic post-infectious disease. Neisseria gonorrhoeae, E. coli, and other bacteria that cause urinary tract infections can also cause epididymitis. Granulomatous epididymitis due to tuberculosis is rare in the developed world but is a cause of infertility in countries with higher burden of disease. Non-infectious causes include generalized diseases such as Behcet's or sarcoidosis. Patients can develop chemical epididymitis from drugs such as amiodarone or due to retrograde flow of urine through the epididymis while exercising or during sexual intercourse, particularly in older men (Nickel, 2003).

Epididymal disjunction and epididymal or ductal atresia are congenital causes of epididymal obstruction and occur during fetal development. The testis and head (caput) of the epididymis both derive from the genital ridge. In contrast, the epididymal body (fundus) shares its origins with the vas deferens, developing from the mesonephric tubules and Wolffian duct. The epididymal caput and fundus join when the rete testis and mesonephric tubules come together starting at 12 weeks of fetal age. In epididymal disjunction, the efferent ducts fail to reach the testis, possibly because they do not properly coil and elongate (Kroovand and Perlmuter, 1981). This failure causes incomplete union of the epididymis and the testis, with the tail, caput or even the entire epididymis totally dissociated with the testis. Epididymal or ductal atresia is thought to occur due to a vascular accident associated with the involution of the mesonephric duct during this same time period (Dickinson, 1973). Both epididymal disjunction and atresia are closely associated with cryptorchidism and patency of the processus vaginalis and are often diagnosed at time of orchiopexy (Marshall and Shermeta, 1979; Kim et al., 2015).

Congenital epididymal obstruction also occurs in Young syndrome. Young – or sinusitis-infertility - syndrome is a rare disorder affecting the respiratory and reproductive systems. The disorder was first described in 1984 (Handelsman et al., 1984). Patients

Fig. 1 Extratesticular obstructive azoospermia.

characteristically have chronic sinusitis, bronchiectasis and obstructive azoospermia caused by epididymal obstruction. Patients may also have structural sperm abnormalities in the axoneme which can cause motion abnormalities. It is believed that the disorder arises from abnormal ciliary function or mucous quality, however the exact mechanism remains unknown.

Patients with epididymal disruption or obstruction typically present with infertility and possibly scrotal pain. It is common for these patients to endorse a history of previous scrotal surgery, epididymo-orchitis, urinary tract infection or sexually transmitted infection. On physical exam, they may have an enlarged, indurated epididymis with palpable cysts. On semen analysis, the classic findings are azoospermia with a normal ejaculate volume. In patients with acquired obstruction, scrotal ultrasound may reveal an enlarged, hypoechoic epididymis consistent with epididymitis (Jhaveri et al., 2010). The diagnosis of epididymal obstruction is often difficult to make. This is especially true in patients with unilateral or partial obstructions. These patients may present not with azoospermia but oligo- or asthenozoospermia. The conclusive diagnosis of epididymal obstruction is typically made at the time of surgical exploration by performing a vasogram (Chan, 2013).

Patients with suspected epididymal obstruction are candidates for surgical reconstruction with vasoepididymostomy. In this procedure, an anastomosis is created between the vas deferens and the epididymis in order to bypass the area of epididymal obstruction. It is a technically challenging operation and more demanding than vasovasostomy (vas to vas anastomosis). During the procedure, fluid from the epididymis is extracted and examined for sperm content. The urologist continues with the vasoepididymostomy only if live sperm are visualized. Vasoepididymostomy is often not technically feasible in patients with congenital disruptions or ductal atresia and is most successful in patients with acquired obstructions. The group most likely to benefit are those with infectious obstructions. In one study, only 52% of patients with clinically suspected epididymal obstruction were identified to have an obstruction at the time of surgery; the remainder had other anatomic abnormalities and most of these were not amenable to repair. The post-operative patency rate ranges in the literature from 50 to 80% with about 60% of men after technically successful vasoepididymostomy having live sperm in their ejaculate (Berardinucci et al., 1998). The natural pregnancy rate is about 30% (Peng et al., 2012).

Vas deferens

Disruption of the vas deferens is almost always intentional, occurring after vasectomy. Another acquired cause of vas obstruction is iatrogenic injury following hernia repair, particularly when a mesh plug is employed. Infertility due to congenital disorders of the vas deferens are also possible.

Congenital unilateral absence of the vas deferens (CUAVD) is an infrequent cause of infertility. The prevalence of CUAVD in published studies is highly variable—from 0.08% to 1.25%. Most recently, a 2016 retrospective chart review of 23,000 patients undergoing vasectomy revealed only 82 men with likely UAVD, a prevalence of 0.36% (Miller et al., 2016). Even when present, the majority of patients are not subfertile. Among subfertile males with CUAVD, the majority have genitourinary anomalies of the contralateral testis or ducts (Schlegel et al., 1996). Just as in CBAVD, congenital unilateral absence of the vas deferens (CUAVD) is associated with CF mutations; the majority of these patients have concurrent occlusion of the contralateral vas and resultant infertility (Mickle et al., 1995). There is also a strong relationship between CUAVD and unilateral renal agenesis, especially in patients without CF mutations. Up to 1/3 of patients with CUAVD also have ipsi- or contralateral renal agenesis (Kolettis and Sandlow, 2002). Because of the strong association, all men with CUAVD should be screened with renal ultrasonography for concurrent renal agenesis. In the absence of such retroperitoneal pathology revealed by sonograms, genetic testing for cystic fibrosis carrier status should then be performed.

Ejaculatory Duct Obstruction

Ejaculatory duct obstruction (EDO) is an uncommon cause of OA, occurring in 1–5% of cases (Meacham et al., 1993; Matsumiya et al., 1994). The classic presentation of these patients is the triad of painful ejaculation, infertility and hematospermia. Patients may endorse a history of prior UTI, epididymitis, perineal trauma or testicular or perineal pain.

EDO can be congenital or acquired and is most commonly due to either cyst formation or postinflammatory change. Mullerian duct (prostatic utricle) or Wolffian duct (diverticular) cysts are typically congenital and occur medially in the prostate between the ejaculatory ducts, obstructing them. Prostatic cysts only rarely cause EDO. When not enlarged, the prostatic utricle is not visible on transrectal ultrasound (TRUS). When enlarged, however, utricle cysts can be visualized with TRUS and are often found incidentally during studies performed for other reasons. If symptomatic, these cysts can contribute to LUTS and cause pain, hematospermia, urinary tract infections, or infertility. Treatment is only recommended in symptomatic patients and consists of either cyst puncture or endoscopic marsupialization (Coppens et al., 2002).

The most common cause of postinflammatory EDO is urethral prostatitis. Postoperative adhesions after TURP are an iatrogenic cause. Other, rarer, causes of EDO include seminal vesicle calculi, calcifications near the verumontanum or congenital ejaculatory duct atresia. About 50% of patients with idiopathic EDO have CF mutations, therefore genetic screening is recommended in all patients with EDO of unclear cause (Jarvi et al., 1995).

Patients with EDO should undergo semen analysis, which typically reveals azoospermia with low semen volume, pH < 7.2 and absence of fructose in the specimen. It is important to screen patients with low ejaculate volume to ensure they are not taking medications that impair ejaculation. Patients presenting with either persistent or recurrent hematospermia should also be evaluated with TRUS. This is the gold standard in diagnosis of EDO. Enlarged seminal vesicles (width > 1.5 cm) or ejaculatory ducts (diameter

> 2.3 cm) on TRUS are suggestive of EDO, especially in combination with visualization of cyst or calcification in the area of the duct. TRUS is also useful to rule out malignancy, which is found in about 4% of patients with persistent hematospermia (Ahmad and Krishna, 2007).

While it was originally described in men with complete blockages, EDO is thought to represent a spectrum of disease. Patients with either unilateral or partial bilateral obstructions may present with oligoasthenozoospermia instead of azoospermia. The diagnosis and treatment of such a condition has not been rigorously studied yet. They may also have normal ejaculate volume. In contrast, patients with complete or functional complete bilateral obstructions present with low ejaculate and azoospermia.

EDO should be treated in men with bothersome ejaculatory or postejaculatory pain, infertility or recurrent/persistent hematospermia. The first step is cessation of all medications that reduce ejaculatory volume or lead to ejaculatory dysfunction. If this is not thought to be the cause, the standard of care for symptomatic patients is a transurethral resection of the ejaculatory ducts (TURED). This is an outpatient procedure during which a cystourethroscope with an electrocautery loop is used to resect the verumontanum in the midline. If the patient has a unilateral obstruction, the verumontanum can be resected only on that side. Another technique is to make multiple incisions in the verumontanum without resecting the structure. It is important to use electrocautery judiciously when achieving hemostasis during these procedures because of the risk of fulgurating and reobstructing the ejaculatory ducts. At the conclusion of the resection, milky fluid is often visualized refluxing from the open ducts; this is a sign that the procedure has been successful. Semen analysis values will improve as early as 2 weeks post-operatively and are followed until they normalize. In studies, 20%–30% of patients were able to achieve pregnancy after TURED with equal outcomes for patients with partial and complete obstruction. Common adverse events associated with TURED include epididymo-orchitis and watery ejaculate. Reobstruction also occurs in a significant minority of patients and may require re-TURED.

Seminal Vesicle

The seminal vesicles produce 80–90% of ejaculate volume, but vesicular obstruction or anomalies are a rare cause of infertility. Seminal vesicle cysts can be congenital and can cause blockage and therefore infertility. When they do occur, the cause is sometimes an ectopic ureter draining into the seminal vesicle from a dysplastic kidney. In fact, the seminal vesicle is the second most common place for ureteric ectopy in men after the prostatic urethra. This association exists because both the ureter and seminal vesicle are derived from a common embryologic mesonephric origin. Even when there is no ectopic ureter, congenital seminal vesicle cysts are associated with unilateral (usually ipsilateral) renal agenesis in the majority of cases (Coppens et al., 2002). These patients should therefore be screened with renal ultrasound (Jhaveri et al., 2010). Acquired seminal vesicle cysts are also possible; these are thought to be secondary to downstream obstruction due to prostatic enlargement, malignancy, or surgery.

The majority of cysts are small (<5 cm) and asymptomatic. Symptoms, if they arise, typically occur in patients between 20 and 40 years of age. Patients may experience dysuria, urinary frequency, perineal pain, epididymitis, post-ejaculatory or scrotal pain and infertility. In most cases, the cyst is palpable rectally. Imaging techniques - including TRUS and less often scan or vasovesiculography - may also be used to visualize the cyst.

Patients with symptomatically obstructing seminal vesicle cysts merit treatment. One option is aspiration of the cyst perineally, transabdominally or transectally. The cyst fluid can then be sent for evaluation for the presence of sperm to aid in diagnosis. Even if aspiration is immediately successful in decompressing the cyst, patients are at high risk of recurrence. Because of this, it is not considered first line management. Depending on the cyst location and size, it is sometimes possible to proceed with transurethral cyst deroofing. This technique has an excellent (75% in one study) success rate of alleviating patients' symptoms when technically possible. If inaccessible transurethrally or if the cyst recurs, open abdominal/pelvic surgery is an option and has an extremely high success rate, but is of course higher risk (Van den Ouden et al., 1998).

Conclusion

Obstruction anywhere along the path of semen formation and ejaculation can lead to infertility. The most common cause of obstructive azoospermia is epididymal obstruction due to infection. Obstructions of the vas deferens, seminal vesicles and ejaculatory ducts are less common but other causes of male infertility.

Primary Ciliary Dyskinesia

Gabriella Avellino and Robert D Oates, Boston University School of Medicine, Boston, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Axoneme The motor unit of the cilia and flagella.

Cilia The hairlike projections on the outside of many cells in the body.

Flagellum An elongated and modified cilium that helps propel a cell.

Intracytoplasmic sperm injection Placement of a single sperm into a harvested egg.

Introduction

Primary ciliary dyskinesia (PCD) is a genetically and phenotypically heterogeneous disease. Ciliary dysfunction and the resultant manifestations that arise characterize this autosomal recessive disorder. The moniker “Kartagener syndrome” is used to describe the clinical triad of situs inversus, chronic sinusitis and bronchiectasis, the underlying defect driving the pathophysiology to be in ciliary structure and function. In 1976, the appellation “immotile cilia syndrome” was used in common parlance to reflect the growing diversity of ciliary-based disease being recognized, one subtype still called “Kartagener syndrome.” Eventually, in addition to static, nonfunctional cilia, scientists observed cilia that were indeed moving in some affected patients, although in an uncoordinated and ineffective manner. Thus, the final and present change to “primary ciliary dyskinesia,” additionally further distinguishing these innate conditions from “secondary cilia deficiency” which occurs in response to chronic infection or inflammation (Leigh et al., 2009; Knowles et al., 2013).

The estimated prevalence of PCD is 1 in 10,000–20,000 births (Goutaki et al., 2017). Cilia have a myriad of crucial and necessary roles in embryonic and fetal development (e.g., proper left–right organ rotation and orientation), childhood health (e.g., proper mucociliary clearance in the respiratory tree and sinus tract), and procreation (e.g., proper sperm motility) (Leigh et al., 2009).

In a study based on an international PCD Cohort of 3013 patients, including 71% from European countries and 17% from America, 49% were male. The median current age of patients was 18 with a range of 1–92 years old. The largest age subgroup was 10–19-year-olds (38%), followed by 20–29-year-olds (18%) and 0–9-year-olds (17%). This group likely underrepresents adult patients and is limited by variability in care and diagnostic tools (Goutaki et al., 2017).

Basic Structure of Cilia and Flagella

Cilia and flagella are hair-like structures that have a configuration and purpose that have remained constant despite evolution over time and across species. Cilia are typically shorter than flagella at 5–10 μm , compared to 50–150 μm in length (Linck et al., 2016). Cilia can be classified into four different subtypes, distinguished by minute changes in axonemal substructure which determine ultimate function and role. The axoneme is the internal motor unit of a cilia/flagellum and is constructed of well-organized microtubules fashioned out of α - and β -monomers of tubulin that comprise the protofilaments (9 microtubule doublets, equally spaced, and centrifugally arranged around a central microtubule doublet pair—the “9 + 2” classic description) and their associated accessory elements (e.g., structural and mechanical braces as well as energy producing ATPases) (Leigh et al., 2009) (Fig. 1).

Motile Cilia (“9 + 2,” Dynein Arms)

Motile cilia facilitate the transport of fluids along the surfaces of upper and lower respiratory epithelium, central nervous ependymal lining, and fallopian tubes. The microtubules of motile cilia reside in a classic 9 + 2 pattern, that is, in cross-sectional image, nine pairs lie on the periphery in a circular fashion around a central pair of microtubules. A complex interaction of outer and inner dynein arm proteins convert the potential chemical energy stored within ATP to mechanical work creating shifting of microtubules relative to one another and, thus, motion. Additional key components are nexin links which connect the adjacent microtubule pairs one to another and radial spokes which secure the central microtubules to those in the periphery. There are approximately 200 cilia per respiratory epithelial cell that beat in a coordinated direction-specific fashion to allow for a stronger forward stroke than back stroke in order to move fluid and mucus and thus toxins and bacteria in a functionally appropriate direction (Knowles et al., 2013).

Fig. 1 A cross sectional diagram through a typical eukaryotic flagellum showing the 9 + 2 arrangement of the microtubules. Also shown are the dynein arms, the nexin links, and the radial spokes.

Nodal Cilia ("9 + 0," Dynein Arms)

Nodal cilia are critical at the embryonic stage to help direct proper right–left orientation and symmetry of the developing internal organs (heart and GI tract) as their movement creates a leftward directional flow of extracellular fluid. Nodal cilia lack the central doublet but do have the peripheral nine doublets and active dynein arms. Situs inversus totalis occurs when all internal organs mal-rotate while isolated dextrocardia refers to a situation in which the heart has rotated to the right while the abdominal viscera is oriented normally (Mirra et al., 2017).

Primary or Sensory Cilia ("9 + 0," No Dynein Arms)

Primary or sensory cilia are expressed on most cells, are nonmotile with a sensory function to receive and transduce local environmental signals. These cells contribute to signaling pathways and cell polarity. Sensory cilia have a structure of 9 + 0, similar to nodal cilia but are without dynein arms. They are found on most cells, and if defective can lead to various pathologies spanning multiple organs, for example, retinitis pigmentosa and adult polycystic kidney disease (Knowles et al., 2013).

Flagella ("9 + 2," Dynein Arms, Additional Periaxonemal Structural Elements)

The flagellum is a ubiquitous, conserved motile structure and is, essentially, the sperm tail in humans. Similar to motile cilia, flagella have a 9 + 2 axoneme, with nine outer microtubule doublets encircling a central doublet. However, the sperm tail contains a number of necessary, additional peri-axonemal elements that provide the structural foundation to generate forward propulsion including fibrous sheath proteins and outer dense fibers. Cilia sway back and forth in an "oar-like" fashion, while flagella beat with a "snake-like motion" (Linck et al., 2016).

Diagnosis of PCD

Due to its clinical heterogeneity, diagnosis can be challenging, expensive and often requires expertise. In 2017, a European task force composed of multidisciplinary clinicians and scientists published the *European Respiratory Society* Guidelines for the Diagnosis of Primary Ciliary Dyskinesia by defining the population for which PCD should be considered and for whom testing should be completed (Lucas et al., 2017). They specify a diagnostic algorithm which may include assessment of nasal nitric oxide (nNO), high-speed video light microscopy (HSVA), and transmission electron microscopy (TEM). The panel did not recommend genetic analysis as a diagnostic screening tool unless the above tests were normal or equivocal in the setting of a strong clinical suspicion. Currently recognized genetic defects diagnose only 50%–75% of cases. Genetic testing may be useful to augment a diagnostic pathway or to prepare for preimplantation genetic diagnosis (vide infra).

Transmission electron microscopy (TEM) evaluates ciliary ultrastructure. Multiple structural defects have been identified in respiratory cilia collected by nasal scrape or bronchial brush biopsy in patients with suspected PCD. Although this was once felt to be the

gold standard for diagnosis, TEM will not reveal an anomaly in approximately 30% of patients with PCD who have normal ciliary ultrastructure (Boon et al., 2014).

An alternative screening method involves evaluating nasal nitric oxide (nNO) levels. Most, but not all, patients with true PCD will have 10%–20% of normal levels. Results may be falsely negative in an acute upper respiratory infection and are not as reliable in children < 6 years of age. The mechanism for the difference in nNO levels between affected and unaffected patients has yet to be identified (Lucas et al., 2017).

A newer technique of high-speed video light microscopy (HVMA) allows for a nonstatic assessment of subtle alterations in ciliary wave form. Similar to TEM, the test is run *ex vivo* on nasal or bronchial respiratory epithelium. Different ultrastructural defects translate into specific patterns of ciliary dyskinesia that can be identified on HVMA (Lucas and Leigh, 2014).

Finally, a seven-point questionnaire (PICADAR) helps predict the likelihood of PCD in a patient referred for persistent wet cough. The variables include full-term gestational age, admittance to a neonatal unit, neonatal chest symptoms, persistent perennial rhinitis, chronic ear, and hearing symptoms, situs abnormalities, and presence of a cardiac defect. A score ≥ 10 predicts >90% chance of testing positive for PCD (Behan et al., 2016).

Additional future directions include immunofluorescence labeling of proteins in cilia to identify ultrastructural abnormalities and radioaerosol mucociliary clearance as an *in vivo* assessment.

Genetic Anomalies Underlying Ciliary and Axonemal Abnormalities in PCD

There are currently 40 known genes associated with PCD and multiple characterized mutations in these genes that code for structural and functional proteins in cilia—not just proteins in the axonemes itself but also proteins involved in the cytoplasmic preassembly of both outer and inner dynein complexes (Guo et al., 2017). In 1999 Pennarun et al. were the first to report a specific gene underlying PCD, through a candidate-gene approach identifying loss of function mutations in *DNAI1* leading to an absence of dynein arms within the axoneme (Pennarun et al., 1999). Deleterious alterations in *DNAI1* and anomalies in the molecular sequence of *DNAH5*, whose product contributes to the configuration of the outer dynein arm, are etiologic in 9% and 21% of PCD cases, respectively. As expected, mutations leading to abnormal outer dynein arm function will result in immotile or markedly slow cilia (Horani et al., 2016). At present, approximately 65% of patients with PCD have identifiable biallelic mutations. Guo et al. identified loss-of-function mutations in $\frac{3}{4}$ consanguineous families (*ARMC4*, *CCNO*, *DYX1C1*) and a missense mutation (*DNAI1*) in the last of the four families they reported on (Guo et al., 2017). Conversely, current genetic analysis will fail to identify a causal abnormality in up to 30% of patients.

The ultimate goal will be to associate the ultrastructural findings detailed on TEM, the specific ciliary dysfunction visualized on HVMA, the measured nNO values and the overall clinical and phenotypic picture of an individual patient with a defined PCD mutation profile. For instance, mutations in *DNAH11* reveal normal TEM findings, abnormal HSVA studies and low nNO. As reviewed by Mirra et al., mutations leading to abnormalities of the central doublet or radial spoke components, such as *RSPH1*, *RSPH3*, *RSPH4A*, *RSPH9*, and those that impact genes controlling the generation of multiple motile cilia, such as *MCIDAS* and *CCNO*, do not lead to laterality defects as nodal cilia do not have, nor require, a functional central doublet (Mirra et al., 2017). Males with *CCDC114* mutations, which impact the outer dynein arm docking factor have normal sperm motility. As the authors note, further genotype: molecular phenotype, genotype: functional phenotype, and genotype: anatomical phenotype correlations need to be pursued and codified.

Although primarily autosomal recessive, X-linked PCD has been described in association with mutations in *RPGR* and *PIH1D3*, the former being found in 20% of all cases of retinitis pigmentosa (Moore et al., 2006; Paff et al., 2017). Paff et al. report on four men with mutations in *PIH1D3*, either maternally inherited or *de novo*. As such, X-linked disease creates a sex-limited phenotypic expression pattern affecting predominantly, if not solely, males.

Prior to completing *in vitro* fertilization, many reproductive groups will perform carrier screening on one of the two members of a couple to determine if the offspring is at risk of an autosomal recessive disease. A few of the expanded tests available will check for *DNAH5*, *DNAI1*, and *DNAH11* (Horani et al., 2016). However, both members of these couples are asymptomatic and these tests have only a screening role. In the case of a symptomatic individual, variable numbers of mutations (up to 36 in one company's PCD panel) may be assayed for with the number increasing over time. "The yield of allele-specific approaches is low in PCD given the high genetic and allelic heterogeneity" (Lucas et al., 2017).

Clinical and Phenotypic Manifestations of PCD

Pulmonary and Respiratory Dysfunction

Defective cilia can lead to disease of the conducting airways, paranasal sinuses, and middle ear (Eustachian tube). As mucociliary clearance is part of a human's primary innate immunity, even though a nonspecific defense mechanism, the most prominent and distressing symptoms of PCD include recurrent to chronic upper and lower respiratory tract infections. Daily nasal congestion, year-round wet cough; chronic rhinorrhea with loss of ability to smell, and chronic otitis media is seen in over 75% of children with PCD and are the signs and symptoms that most often lead to evaluation and diagnosis (Mirra et al., 2017).

Situs Inversus Totalis

Situs inversus totalis describes the anatomical configuration of completely transposed thoracoabdominal viscera to a mirror position of normal, that is, the heart is rotated to the right side (dextrocardia) and the abdominal organs are flipped left-to-right and vice versa. This happens in approximately 50% of PCD cases, implying a random axis orientation when the normal embryonic, ciliary-directed signal is not present—a crucial function of cilia within the embryonic node. Heterotaxy represents a spectrum of laterality derangements of any of the internal thoracoabdominal organs and is seen in approximately 6% of individuals who do not have situs inversus totalis (Leigh et al., 2009). Certain regions of the brain, specifically the frontal and occipital petelia, may be subject to ciliary orientation while the lateralization of language may be controlled via a different mechanism (Kennedy et al., 1999).

Male Infertility

Most, but not all, men with PCD experience infertility as sperm motility is necessary for spermatozoa to swim up the female reproductive tract in order to meet and penetrate the oocyte. Often, ejaculate sperm count and morphology are within normal ranges but there is a complete absence of movement. Semen volume should be normal as the seminal vesicles, which are responsible for 70% of the ejaculate volume, are unaffected. The semen pH should be alkaline as all of the alkalinity arises from the secretions of the seminal vesicles which, again, are without defect or dysfunction. Testis size reflects sperm production capacity and so is normal. The epididymides and vasa are palpably present and unobstructed in PCD. The hypothalamic-pituitary-gonadal axis is optimal. It is the sperm axonemes themselves that are affected, thereby limiting sperm motility, propulsion, and forward progression, the proximate cause of the couple's infertility. Ji et al. provide a comprehensive description of the numerous genes (their name, axonemal location, the defect arising when they are dysfunctional, the infertility phenotype, and the chromosomal location) that have been identified so far that affect axonemal structure or function and result in, at least, male infertility (Ji et al., 2017).

Treatment Options for Reproductive Failure in Men With PCD

As reviewed by Ebner et al., data on fertility outcomes in couples with a male partner afflicted with PCD are limited and are generally small series or case reports (Ebner et al., 2015). However, what is clear is that intracytoplasmic sperm injection, an advanced reproductive technique in which an individual viable spermatozoon is placed directly into an individual oocyte via micromanipulation (ICSI), is necessary to effect fertilization, embryo development, and pregnancy. Although Davila Garza and Patrizio state, “the fertilization potential and live-birth rates are close to that obtained from nonspecific causes of sperm defects,” others would disagree (Davila Garza and Patrizio, 2013). It is unclear, therefore, whether sperm from the generic man with PCD will be able to generate these results consistently. Adjunctive techniques may be required to select viable sperm, since the most obvious sign—motility—is absent. These include selecting sperm to use by noting sperm tail coiling in a hypoosmotic solution which indicates viability, noting sperm tail flexibility upon flicking the sperm with the microinjection pipette which indicates viability, of stimulating the tiniest bit of motion with theophylline or pentoxifylline which indicates viability (Kordus et al., 2008). Some authors suggest the use of testicular sperm rather than ejaculate sperm as the source of the male gamete during ICSI, positing that it is more likely the embryologist will be able to select viable and healthy sperm from harvested testis tissue than from the mixture of viable and nonviable nonmotile sperm in the ejaculate. In this regard, an open operative approach to obtaining testis tissue or a percutaneous aspiration are both appropriate (Hayden et al., 2016). Finally, Ebner et al. report on using Ca^{2+} -ionophore to activate the oocyte, a normal function of the spermatozoan which, they speculate, may be deficient in some PCD cases (Ebner et al., 2015). They describe a twin live-birth to a couple in whom conventional ICSI did not result in fertilization but that Ca^{2+} -ionophore treatment did successfully. McLachlan et al. report on a variant of PCD in which not only were the sperm immotile but they were also structurally quite abnormal in the tail and midpiece (McLachlan et al., 2012). Testis tissue was used as the source of spermatozoa and they selected only relatively normal appearing gametes. No pre-ICSI genetic analysis was performed but the authors do caution that there would be concern of transmission to the offspring. In their case, the daughter born showed no evidence of an inherited ciliopathy.

As above, couples interested in conception should have genetic counseling. All children of individuals with PCD will at the very least, be obligate simple heterozygotes (carriers). If the partner of a PCD male is shown to be a carrier as well, preimplantation genetic screening may be applied to prevent delivery of an affected offspring. In the case of X-linked disease, couples may choose to only transfer male embryos (who will be free of disease as they inherit the paternal Y chromosome and not the paternal X chromosome) and not female embryos who will then be burdened with the potential, in their own future, to bear sons afflicted with PCD.

There is no cure for PCD. Treatment is not specific to PCD and is primarily symptomatic, based on strategies of care developed for patients with cystic fibrosis or idiopathic bronchiectasis. Treatment focus is to prevent exacerbations and slow the progression of pulmonary disease. Care includes clearance of airway by inhalers, nebulizers and chest physiotherapy and close monitoring for need of antibiotics. Exposure to inflammatory triggers, including second-hand smoke, should be limited. Patients should be up to date with immunizations, especially pneumococcal, and influenza. In addition to better symptom management, novel therapeutic strategies are being investigated. For example, identification of gene defects hopefully will allow for gene editing to reestablish gene function and consequently normal ciliary function and motility (Lai et al., 2016). Care is often multidisciplinary, requiring input from pediatricians, neonatologists, pulmonologists, chest physiotherapists, cardiologists, otolaryngologists, geneticists, radiologists, and urologists.

Conclusion

Primary ciliary dyskinesia is a group of disorders based upon structural and functional defects in the hair-like projections that are on many embryonic, fetal, and adult cells. As such, the respiratory and sinus systems are severely affected and typically lead to clinical diagnosis. There are a variety of tests being employed in an adjunctive fashion, with genetic testing playing only a confirmatory role in certain cases. Male fertility is often completely compromised as the motility of the sperm, necessary for the sperm to travel to and penetrate the egg, is absent or significantly deficient. Newer therapies, however, can help male patients achieve biological paternity. These include a variety of ways to identify viable and healthy sperm that can be placed, individually, inside a harvested egg to effect fertilization, embryo development and term birth. The genetic basis is varied as multiple genes are involved responsible for the numerous parts of the motor apparatus of the cilia and sperm tail. They are being identified and understood slowly but steadily with continued research. When contemplating treatment of male infertility in a PCD patient, it is important to recognize, if possible, the genetic mechanisms underlying the axonemal defect in that individual man so as to be able to prevent transmission to his offspring (or their offspring). The ultimate goal will be to link the clinical and phenotypic features to the genetic anomaly and provide more precise and directed treatment.

Reproduction and Its Global Implications

In the beginning of the 21st century, improvements in reproductive health was one of eight goals specified in the United Nations Millennium Development Goals (http://www.who.int/topics/millennium_development_goals/en/). A major aspect of reproductive health includes infertility that affects up to 15% of the population worldwide and causes emotional distress in couples and families. Access to contraceptive options was also outlined within the goal of reproductive health as unplanned pregnancies place undue burden on women and continued population growth places more strain on Earth's limiting resources. In this chapter, we will discuss sperm function and formation, and how basic research into spermatogenesis has provided insights in both infertility and potential male contraceptives.

Sperm Function

Spermatozoa (sperm) are remarkable cells considering their role and importance to sexually reproducing species. Sperm are delegated with the task of carrying the haploid genome of the male to the oocyte of the female, a journey along the mammalian female reproductive tract that is up to several thousand times the length of sperm. Remarkably, sperm undergo this journey in the absence of transcription and protein production. Of the millions of sperm, only a small number will reach the vicinity of the egg. These sperm must then penetrate the layer of ovarian granulosa cells and the zona pellucida surrounding the oocyte, and undergo the acrosome reaction to expose receptors that allow the sperm to bind the oocyte and promote fusion with the plasma membrane. Only after completion of their journey and fusion with the egg can development begin. Even in the case of healthy sperm, many sperm will not complete their task due to the strenuous journey. Any defect in sperm formation, production, or energy supply will exacerbate the difficulty of completing their journey. It is no surprise then that any problems in the production of healthy sperm lead to infertility. Conversely, disrupting sperm production and function has been an avenue to pursue male contraceptives, which we will discuss at the end of this section (Table 1).

Spermatogenesis 101

Spermatogonia and Mitosis

The production of sperm begins within the seminiferous tubules of the testis (Fig. 1A). Male germline stem cells (GSCs) are rare cells located at the periphery of the tubules. GSCs divide mitotically to replenish the stem cell pool and generate daughter cells that will

differentiate. The GSCs and their mitotically dividing daughter cells are referred to as spermatogonia (De Rooij, 2017). Spermatogonia will continue to undergo several rounds of mitosis with incomplete cytokinesis to generate a syncytium of cells connected by intracellular bridges. Intracellular bridges allow an exchange of materials and cellular signals that coordinate further development, and absence of intracellular bridges blocks sperm development prior to meiotic division (Greenbaum et al., 2006). In many systems, the dividing spermatogonia have been well characterized and named. For example, mouse GSCs and their initial daughter cell are referred to as A_{single} for a spermatogonia that is single and not interconnected with other cells. The A_{single} daughters divide to form a pair of joined cells called A_{paired} . With each subsequent division, the number of connected cells increases, while the developmental potential becomes restricted to the meiotic program. In the mouse, there can be 9–11 mitotic divisions of spermatogonia before proceeding to the next phase of spermatogenesis.

Spermatocytes and Meiosis

When spermatogonia finish dividing mitotically, the cells undergo a pre-meiotic S-phase and initiate meiosis. Meiotically dividing cells are referred to as spermatocytes (Russell et al., 1990). Spermatocytes begin to move away from the periphery of the seminiferous tubules and towards the lumen. In meiosis, homologous chromosomes pair and are held together by a protein complex called the synaptonemal complex. During the pairing of chromosomes, double strand break formation, break repair, and homologous recombination occur, generating genomic diversity by recombining parental chromosomes. In many species, recombination is required for meiosis to proceed properly. Recombination is important because the recombination spot, visualized as chiasmata, allows homologous chromosomes to properly align at the metaphase plate and divide, and is also responsible for generating genetic diversity that drives evolution. Once pairing and recombination have completed, spermatocytes undergo two rounds of division, with the first round separating homologues and the second round separating sister chromatids to generate haploid cells.

Spermiogenesis

The haploid cells generated by the meiotic divisions are called round spermatids due to their characteristic round shape. Round spermatids will differentiate into spermatozoa in a process called spermiogenesis (Russell et al., 1990). Multiple morphological changes occur during spermiogenesis which include flagellum formation, acrosome development, cytoplasmic loss, and reshaping of the nucleus. The flagellum of spermatozoa includes accessory structures in addition to the axoneme, the 9 + 2 microtubule core found in cilia and flagella in other eukaryotes. In mammalian systems, the flagellum can be divided mainly into the midpiece and principal piece (Fig. 1B). The midpiece is proximal to the nucleus and contains outer dense fibers surrounding the axoneme with tightly packed mitochondria. The principal piece is devoid of mitochondria but contains outer dense fibers surrounding the axonemal core, which in turn is encased by the fibrous sheath. Early in spermiogenesis, the acrosomal vesicle initially forms by the fusing of pro-acrosomal vesicles derived from the Golgi apparatus. As more vesicles fuse, the acrosomal vesicle grows and forms a cap-like shape (the acrosome) around the nucleus. Within the vesicle, there are proteases and receptors that allow for sperm-egg recognition. As spermatids progress through development, the nucleus and acrosome shift position to leave most of cytoplasm on one side. The cytoplasmic remnants (also called the residual body) will be lost at the end of spermiogenesis and be phagocytosed by

Sertoli cells. The loss of cytoplasm generates the streamline shape of spermatozoa. Midway through spermiogenesis, histone proteins are replaced by transition proteins, highly basic proteins, that are replaced themselves by protamines. Protamines are also highly basic proteins that allow for greater compaction of chromatin. Chromatin compaction along with the cytoskeleton generate the peculiar nuclear morphology of sperm. The tight compaction of the nucleus also prohibits transcription. In the final process of spermiogenesis, the spermatozoa are released into the lumen of the seminiferous tubules in a process called spermiation. Released spermatozoa are transported to the epididymis. During transit through the epididymis, spermatozoa acquire motility and fertilization ability. It is in the cauda epididymis where mature sperm are stored.

Defects in Sperm Number or Function

Azoospermia

Azoospermia is the condition of complete absence of sperm in the ejaculate. In infertile males, approximately 15% display azoospermia. Azoospermia can be subdivided into two broad categories, obstructive azoospermia (OA) and non-obstructive azoospermia (NOA). OA is the results of a blockage within the excurrent duct system. For example, mutations in *CFTR* result in congenital bilateral absence of the vas deferens in males homozygous for these mutations (Grangeia et al., 2007). NOA can result from primary, secondary, or incomplete testicular failure. Among males with azoospermia, 60% is due to OA and 40% due to NOA. Between OA and NOA, NOA presents with the most problems in conception rates using in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI) because NOA is more often associated with spermatogenesis failure leading to production of few or no sperm.

Primary and secondary testicular failure result in the inability of testosterone production required for testis development; however, the source of the failure is what differentiates the two. Primary failure is the inability of the testis itself to produce testosterone while secondary failure results from defective hormonal signaling from the pituitary/hypothalamus axis which in turn instructs the testis to produce testosterone. Klinefelter Syndrome (XXY karyotype) is one condition that leads to primary testicular failure as the testis are underdeveloped with low levels of testosterone production. Very rare mutations in the chromatin protein CHD7 leads to CHARGE Syndrome, with one symptom being defective gonadotrophin releasing hormone production resulting in secondary testicular failure (Matzuk and Lamb, 2008).

Incomplete testicular failure presents with normal hormonal levels (i.e., FSH) with either small testis volume or normal testis volume. In these cases, maturation arrest and defective spermatogenesis can be present. Polysomy of the sex chromosomes (XXY, XYY, etc) and microdeletions on the Y chromosome are a common cause of NOA and were the first genetic abnormalities found in azoospermic patients (Miyamoto et al., 2015). Regions on the long arm of the Y chromosome that were commonly deleted in patients with azoospermia, are called azoospermia factor (AZF). Within this region, a testes specific RNA binding protein called Deleted in Azoospermia (*DAZ*) was identified as the first gene linked to patients with azoospermia. Since the discovery of *DAZ*, several genes in the AZF region and genes on the autosomes have been identified that lead to azoospermia when deleted. For example, deletion of *DBY*, a gene located in the AZF region, leads to seminiferous tubules devoid of developing gametes, which is referred to as a "Sertoli-cell only" phenotype. Mutations in genes essential to meiosis (such as *SYCP3*, *SYCP1*, *MLH1*, and *MYBL1*) lead to a meiotic arrest phenotype (Matzuk and Lamb, 2002, 2008). Genes essential in post-meiotic development show a round/elongated spermatid arrest. Deletions in *CREM*, considered the "master regulator" of round spermatid development, lead to an arrest in round spermatids (Matzuk and Lamb, 2002, 2008).

Oligozoospermia

Oligozoospermia is defined as decreased numbers of sperm in the ejaculate (<15 million sperm/mL), which is further subdivided depending on the number of sperm into mild (10–15 million sperm/mL), moderate (5–10 million sperm/mL), and severe (<5 million sperm/mL). Oligozoospermia can be considered as a less severe form of azoospermia, as the same mutations found in azoospermic patients can cause oligozoospermia in others. For example, the same deletions in the AZF region can also manifest as severe oligozoospermia in some patients. There are examples of gene deletions that have so far been specific to oligozoospermia. Deletions in *KLHL10* have been found in patients with oligozoospermia (Matzuk and Lamb, 2008).

Teratozoospermia

Teratozoospermia is a condition characterized by the presence of spermatozoa with abnormal morphology. In monomorphic teratozoospermia, macrozoospermia and globozoospermia are well-recognized categories (Coutton et al., 2015; De Braekeleer et al., 2015; Ray et al., 2017).

Macrozoospermia

Macrozoospermia is a very rare condition observed in <1% of infertile men and is characterized by oversized misshapen heads and multiple flagella. The spermatozoa of macrozoospermia patients often exhibit unusual number of ploidy, especially four sets of chromosomes instead of normal one set of chromosomes. In 2007, a genome-wide microsatellite analysis revealed mutations in *AURKC* in macrozoospermic men. *AURKC* is a component of the chromosomal passenger complex that regulates mitotic and

meiotic events including chromosome segregation. AURKC dysfunction leads to uneven chromosome segregation and improper cytokinesis during meiosis of spermatogenesis. Unlike human cases, *Aurkc* KO male mice are subfertile but exhibit defective nuclear chromatin condensation and acrosome detachment and malformation. This mild phenotype in mice may be due to compensation by *Aurkb* that is strongly expressed in the mouse testis.

Globozoospermia

Globozoospermia is also a very rare condition observed in less than 0.1% of infertile men and is characterized by round-headed spermatozoa lacking the acrosome and is accompanied by an abnormal nuclear shape and an unusual arrangement of the sperm mitochondria. Mutations in genes such as *DPY19L2*, *PICK1*, *ZBPB*, and *SPATA16* were reported in globozoospermic men and, among these genes, *DPY19L2* is mutated most frequently. The cellular function of *DPY19L2* was analyzed using *Dpy19l2* KO mice that also exhibit male sterility due to globozoospermia. *DPY19L2* is localized in the inner nuclear membrane of the spermatids and is essential for the stabilization of both the nuclear dense lamina and the junction between the nuclear envelope and the acrop-laxome, a structure that anchors the developing acrosome to the nuclear envelope. In addition to *Dpy19l2* KO mice, *Pick1* KO and *Zbpb* KO male mice are infertile due to globozoospermia, indicating that the process of acrosome formation is conserved well between humans and mice. There are more KO mouse lines that are reported to have globozoospermia such as *Csnk2a2*, *Hrb*, *Gopc*, *Gba2*, and *Spaca1* (Fig. 2A). So far, these genes have not been linked to human cases yet.

Asthenozoospermia

Asthenozoospermia is a condition characterized by reduced sperm motility (Coutton et al., 2015; Ray et al., 2017). Complete asthenozoospermia that shows 100% immotile spermatozoa is found at a frequency of 1 in 5000 men. Asthenozoospermia is often observed in men with primary ciliary dyskinesia (PCD), or immotile ciliary syndrome, because both cilia and sperm flagella utilize a common 9 + 2 axonemal structure for their motility. PCD is characterized by congenital impairment of mucociliary clearance and is estimated to be found at a frequency of 1 in 16,000 births. A multitude of genes that constitute the 9 + 2 axoneme were found to

Fig. 2 Examples of sperm defects. (A) Globozoospermia. Sperm from control (Ctrl) and *Spaca1* KO mice were observed using scanning electron microscopy. *Spaca1* KO sperm show abnormal head morphology. (B) Dysplasia of the fibrous sheath. Sperm from Ctrl and *Cabyr* KO mice were observed using transmission electron microscopy. The fibrous sheath (FS) is disrupted in the *Cabyr* KO sperm. (C) Asthenozoospermia. Sperm motility of Ctrl and *Ppp3cc* KO mice were observed. Images of moving flagella were taken at 200 frames per second and were superimposed. *Ppp3cc* KO sperm exhibit impaired motility associated with a rigid midpiece.

be associated with PCD including asthenozoospermia. For example, mutations in *DNAH11* that composes a dynein arm, a motor apparatus in the axoneme, were found in PCD men.

Another cause of asthenozoospermia is dysplasia of the fibrous sheath (DFS). The fibrous sheath (FS) is an accessory structure that surrounds the axoneme in the principal piece of the flagellum. DFS is characterized by disrupted FS, leading to impaired sperm motility because not only does the FS regulate the degree of flagellar flexibility, but also acts as a scaffold for several signaling and/or metabolic pathways. Many components of FS have been identified, such as AKAP3, AKAP4, CABYR. While analyses of *Akap3* KO mice have not been reported yet, KO male mice of *Akap4* and *Cabyr* have been reported to be infertile due to disrupted FS organization (Fig. 2B), suggesting that mutations in these genes may cause DFS in humans. Indeed, deletions in *AKAP3* and *AKAP4* were described in some DFS patients.

In addition to structural defects found in the axoneme and fibrous sheath, functional defects in flagella may also cause asthenozoospermia (Ray et al., 2017). KO mouse lines that show normal flagellar structure but were infertile due to impaired sperm motility were reported in studies of mouse *Catsper1*, *Ppp3cc*, *Gapdhs*, *Ldhc* (Fig. 2C). CATSPER1 and PPP3CC are involved in calcium signaling, and GAPDHS and LDHC are metabolic enzymes. CATSPER1 is a component of a calcium channel localized in the principal piece of the flagellum and is necessary for hyperactivated motility. The pore-forming region of the calcium channel is thought to be composed of four proteins, CATSPER1–4. If any one of these proteins is deleted in mice, the whole channel is disrupted, leading to a decreased motility phenotype. In humans, mutations in *CATSPER1* and *CATSPER2* were identified in asthenozoospermic men.

Unexplained Male Infertility

When semen analyses are normal and female infertile factors are ruled out, the patients are categorized as having unexplained male infertility (UMI) (Esteves et al., 2014). UMI is observed at varying frequencies that range from 6% to 27%, suggesting evaluation criteria can account for the varying frequencies. As the name indicates, causes of UMI are unknown, but recent progress in basic research using KO mice reveals genetic factors that contribute to male infertility that cannot be identified by standard semen analysis. Because assisted reproductive techniques (ART) such as ICSI can often solve UMI, detailed analyses of the causes tend not to be performed. However, basic research including genome sequencing may lead to the development of new methods to evaluate UMI easily and inexpensively, which may help not only understand the causes but also promote cost-effective and low-invasive treatments.

Sperm migration in the female reproductive tract

There are KO mice that show normal sperm morphology and motility but whose spermatozoa cannot pass through the utero-tubal junction (UTJ) of the female reproductive tract (Okabe, 2015). So far, there are more than 10 genes reported, such as *Adam2* and *Ace*, disruption of which causes UTJ migration defects. The spermatozoa of these KO mice exhibit defective binding ability to the zona pellucida (ZP, an extracellular matrix that surrounds the oocytes) as well, suggesting that there is a common mechanism that regulates UTJ passage and ZP binding. When IVF was performed using cumulus-intact oocytes, the oocytes can be fertilized normally, indicating that the cause of infertility is the UTJ migration defect but not impaired ZP binding ability. Therefore, IVF may be an effective way for ART if mutations were found in these genes of infertile men.

Sperm-egg fusion

IZUMO1 is a single transmembrane protein localized to the sperm head (Inoue et al., 2011). The spermatozoa of *Izumo1* KO mice look normal and move vigorously but cannot fertilize oocytes due to impaired sperm-egg fusion. This infertility can be rescued by bypassing the fusion process with ICSI. By blocking human IZUMO1 function with an antibody against IZUMO1, the necessity of human IZUMO1 for sperm-egg fusion was demonstrated, but mutations in *IZUMO1* have not been reported in infertile men yet.

Oocyte activation

After fertilization, oocytes need to be activated by sperm-derived factors (Swann and Lai, 2016). There are two candidate activating protein factors, namely PLCZ and PAWP. Mutations in *PLCZ* were found in infertile men whose sperm fail to fertilize eggs even after ICSI because oocytes cannot be activated by the injected spermatozoa. In this case, it may be necessary to activate eggs artificially, for example, using *PLCZ* mRNA or strontium when performing ART. Intriguingly, *Plcz* or *Pawp* KO male mice were generated recently and were subfertile and fertile, respectively, suggesting that there are different oocyte-activating mechanisms that are not related to PLCZ or PAWP, at least in mice.

Summary and Prospects

From single spermatogonia to the streamlined, haploid spermatozoa, spermatogenesis is a complicated process that produces gametes capable of delivering the haploid male genome to the egg (Matzuk and Lamb, 2002, 2008). In some infertile men, problems in sperm production have been identified. Advances in genomic and exome sequencing has accelerated the discovery of genes associated with infertility observed in these men. The mouse has been a powerful model in assigning genes identified from patients as functioning in specific stages of spermatogenesis. The development of CRISPR/Cas9 genome editing technology has further

accelerated the production of gene ablation and point mutation studies in the mouse (Miyata et al., 2016). Research in identifying male infertility genes has increased the number of potential candidates for contraceptives. For example, a calcium signaling gene (PPP3CC), essential for male fertility, has been shown to be a potential contraceptive target (Miyata et al., 2015). FK506 and cyclosporin A are drugs that target the calcium signaling complex formed by PPP3CC. When administering these drugs, male mice become infertile after 2 weeks with no changes in mating behavior. Mice administered with these drugs produce sperm that have defects in motility, mimicking the asthenozoospermia seen in some infertile male patients. Remarkably, the defects in motility disappear in mice when the drug is withdrawn, leading to perfectly fertile mice. Unfortunately, calcium signaling is important in the immune system, and FK506 and cyclosporin A are powerful immunosuppressant drugs which precludes them from being utilized as a male contraceptive. Next generation drug screening offers the possibility of identifying more selective contraceptive drugs.

Despite these advances in understanding spermatogenesis and its role in explaining male infertility, many challenges remain. While basic research has explained some of the infertility seen in men, there is still a significant percentage of infertile men whose etiology is unknown. It is suspected that undiscovered genetic lesions/gene mutations will provide clues in explaining these cases. The problem of identifying genes essential for male fertility is confounded by the discovery that over 1000 genes are specifically expressed in the testis. We live in exciting times as CRISPR/Cas9 is increasing the pace of discovery in the complicated process that is sperm production and function (Miyata et al., 2016).

MEDICAL CONDITIONS

Medical Conditions and Male Reproductive Medicine: An Overview

Isaac Lam and Robert E Brannigan, Northwestern University, Evanston, IL, USA

© 2018 Elsevier Inc. All rights reserved.

Glossary

- Azoospermic** Lack of viable sperm in semen.
- Bilateral** Involving both sides.
- Contralateral** Involving the opposite side.
- Ejaculatory duct** Formed by the seminal vesicle joining the vas deferens.
- Epididymis** Tube which connects testicle to vas deferens.
- History** Medical history of patient.
- Hernias** Organ abnormally rupturing through breach in tunica vaginalis.
- Hydroceles** Fluid accumulation in body cavity.
- Ipsilateral** Involving the same side.
- Karyotype** Appearance and number of chromosomes in eukaryotic cell nucleus.
- Libido** Sex drive.
- Physical exam** Physical investigation of patient body for disease.
- Spermatic cord** Structure that includes the vas deferens and tissue surround it.
- Spermatogenesis** Production of mature spermatozoa.
- Unilateral** Involving one side only.
- Urethra** Duct from the bladder that delivers urine out of the body.
- Vas deferens** Duct from the testicle to the ejaculatory duct that delivers sperm.

Introduction

Although the societal narrative of infertility typically revolves around women unable to bear children, studies have demonstrated that males contribute in approximately half of all infertility cases. The disease of infertility has a widespread impact, afflicting about one in every seven couples ([Agarwal et al., 2015](#)). This condition can be devastating to patients, causing excessive stress and low self-esteem, especially in cultures where self-worth or masculinity is closely tied to the ability to reproduce. In addition to the psychological consequences of infertility, the disease proves to be costly from an economic standpoint as well. The Urologic Diseases in America (UDA) Project estimates that in 2000 alone, \$17 million were used to treat male infertility. Accounting for the cost of assisted reproductive technologies for the female partner that often comes with treating male infertility, the total price tag of male reproductive medicine amounts to a substantial \$18 billion over the course of one year ([Meacham et al., 2007](#)).

In a normal couple, the chance of pregnancy with unprotected intercourse is about 25% per month and 90% per year. In contrast, nonazoospermic infertile couples have a drastically lower pregnancy rate at about 1–3% a month. Despite these low success rates, about a third of infertile couples can still eventually conceive without any treatment ([Dubey and DeCherney, 2012](#)). By definition, patients are typically considered infertile after a full year of unprotected sex without pregnancy. However, because most couples that have not conceived after 6 months will not be able to in the future, physicians often begin evaluating the patient at this point in time.

To help guide physicians and improve quality of care, the American Urological Association and the American Society for Reproductive Medicine have developed recommendations for the evaluation of male infertility, including history taking, the physical exam, semen analysis, and specialized testing. If etiology of the disease is known, the physician subsequently treats the underlying pathology. If etiology is unknown, the physician and patient typically discuss other available options such as intra-uterine insemination, in vitro fertilization, intracytoplasmic sperm injection, donor insemination, and adoption ([Gangel et al., 2002](#)).

Childhood Illnesses and Conditions

Certain childhood illnesses or developmental abnormalities can later present as infertility in male patients. This section of the article will provide an overview of some of these conditions, including torsion, cryptorchidism, and hypospadias.

Hypospadias and Epispadias

In some patients the opening of the urethra is abnormally positioned on either the ventral or dorsal side of the penis, conditions known as hypospadias and epispadias respectively. Both can lead to infertility if semen is deposited too distally in the vagina as a result of the anatomical abnormality. Although both conditions have seemingly similar names and presentations, the underlying pathophysiology is largely different. Hypospadias are typically caused by genetic polymorphic mutations and environmental factors such as maternal hypertension and low birth weight (Macedo et al., 2012). On the other hand, epispadias are the mildest form of the bladder–exstrophy–espadias complex (BEEC), which encompasses a variety of presentation from failed closure of the lower abdominal wall or bladder. Surgical treatments are available for both hypospadias and epispadias (Ludwig et al., 2009).

Testicular Torsion

Most commonly observed immediately after birth and during puberty, testicular torsion occurs when the spermatic cord twists, limiting blood supply to the testicle and thus causing ischemia. Torsion typically presents as an acute severe testicular pain often associated with nausea and vomiting. Interestingly, biopsies of the contralateral testicle in patients that have experienced torsion reveal abnormal findings as well, indicating that pre-existing testicular conditions may predispose patients to torsion. Treatment includes surgical detorsion to restore blood flow and orchidopexy (anchoring of the testicle to the dartos muscle) in order to minimize the risk of recurrent torsion (Shimizu et al., 2016).

Intersex or Disorders of Sexual Development

Genetic mutations in the sex chromosomes can lead to atypical development of internal or external reproductive organs. In the past, disorders of sexual development (DSD) were divided into four separate categories: male pseudohermaphroditism, female pseudohermaphroditism, true hermaphroditism, and gonadal dysgenesis. Currently, the nomenclature for characterizing DSDs includes the karyotype and the molecular basis of the defect. Treatment can range from hormonal to surgical, with the end goal of reversing the phenotypic abnormalities caused by the genetic defects (Kim and Kim, 2012).

Cryptorchidism

Although failure of the testes to descend is extremely common, the condition typically self resolves. Testes fail to descend in about 4% of newborns, but by age one, only slightly more than 1% of infants remain cryptorchid. For infants in whom the defect does not self-correct, orchiopexy is performed to permanently secure the testicle within the scrotal compartment. Cryptorchidism can present unilaterally or bilaterally, with the bilateral form presenting about twice as commonly as unilateral cryptorchidism. While unilaterally cryptorchid patients have fertility rates similar to the norm, bilaterally cryptorchid patients have substantially lower rates at around 50–60% (Fawzy et al., 2015).

Microductal Aplasia

Failure of the vas deferens to develop can occur unilaterally or bilaterally, each with a unique pathophysiological etiology. Congenital unilateral absence of the vas deferens (CUAVD) typically occurs due to abnormalities in mesonephric duct development. The mesonephric duct evolves into the epididymis, vas deferens, and ejaculatory duct, and thus CUAVD may present with defects in those anatomical parts as well. Because the mesonephric duct plays a role in renal development, CUAVD may suggest concurrent ipsilateral renal agenesis (Weiske et al., 2000).

In contrast, congenital bilateral absence of vas deferens (CBAVD) is typically associated with mutations in cystic fibrosis transmembrane conductance regulator (CFTR) or other genes that regulate mesonephric duct maturation. Cystic fibrosis is an autosomal recessive disease. While patients with just one abnormal copy of the CFTR gene typically do not have cystic fibrosis, they often have CUAVD or CBAVD. At this point in time, over 1000 CFTR genes have been identified. The most common gene mutation in patients with cystic fibrosis, CUAVD, and CBAVD is delta-F508 which involves a deletion of phenylalanine at the position of 508 in the protein sequence. Because gamete production remains normal in most patients with CBAVD, reproduction can still be achieved through ICSI using surgically extracted sperm (Weiske et al., 2000).

Systemic Diseases and Illnesses

Diabetes Mellitus

With 300 million individuals projected to have diabetes mellitus worldwide in 2025, the number of cases of diabetes-linked male infertility will continue to grow. Diabetes can lead to male infertility through a myriad of mechanisms. Leydig cells normally produce testosterone in response to luteinizing hormone (LH), but diabetes can result in dysfunction of Leydig cells leading to low testosterone levels, resultant high LH levels, and primary testicular failure. Secondary testicular failure, marked by low testosterone and LH levels, can also arise from diabetes via diabetes induced changes affecting the hypothalamic-pituitary-gonadal axis. In addition to causing endocrine changes, diabetes can alter sympathetic nerves innervating the reproductive system causing retrograde ejaculation or complete failure of emission. It is important to note that some studies have found that tight regulation of DM leads to diminished impact on male reproductive health (Sexton and Jarow, 1997).

Hypogonadism

Cases of low testosterone can be categorized into two types: hypergonadotropic hypogonadism and hypogonadotropic hypogonadism. As described in the previous section, hypergonadotropic hypogonadism occurs when Leydig cell dysfunction leads to low testosterone and high LH levels. In some cases this dysfunction can occur concomitantly with pituitary dysfunction, resulting in lower than expected LH levels. While treatment options for low testosterone include testosterone replacement therapy, this treatment should not be provided to a man actively trying to conceive as this treatment suppresses intratesticular testosterone levels, spermatogenesis, and commonly renders a patient infertile (Hohl, 2017).

Hypogonadotropic hypogonadism develops when the pituitary gland fails to secrete sufficient amounts of LH and follicle stimulating hormone (FSH). Kallman syndrome is a form of hypogonadotropic hypogonadism, a disease that commonly presents with loss of smell in addition to low serum LH and FSH levels. In most cases, patients are treated with human chorionic gonadotropin (hCG) and recombinant FSH (rFSH) to directly replace LH and FSH respectively. Treatment of milder forms of hypogonadotropic hypogonadism can sometimes include aromatase inhibitors and anti-estrogenic drugs, which have pituitary stimulating effects (Hohl, 2017).

Infection and Inflammation

Common infectious organisms that target the male reproductive system include *Escherichia coli*, *Pseudomonas aeruginosa*, *Klebsiella*, *Neisseria gonorrhoeae*, and *Chlamydia trachomatis*. These organisms can infect the urethra, prostate, epididymis, and testis, although infection of the testis occurs quite infrequently. Infection results in infertility through either functional or anatomical means. Functional impairment arises when an immunological response triggered by the infection induces spermatogenic dysfunction. Anatomical abnormalities leading to infertility can involve the narrowing of a duct in the reproductive system, e.g. the epididymis, vas deferens, or ejaculatory duct. Numerous studies have described the detrimental effects of inflammation on fertility in the setting of infection, but inflammation alone without clear evidence of infection can also have substantial negative effects on both sperm production and sperm function (Niederberger, 2012).

Cancer and History of Cancer Treatment

While it is probably more apparent that treatments targeting malignant growth can have deleterious effects on male reproductive health, cancer itself can impact fertility through various mechanisms. Spermatogenesis requires a precise balance maintained by the hypothalamus, pituitary gland, and testes that is often disrupted by cancer processes. Immune responses that help curb the progression of cancer can unfortunately have negative repercussions for fertility. Systemic conditions such as infection and malnutrition induced by cancer can upset homeostasis and ultimately damage the reproductive system. Even psychological issues such as anxiety and depression specifically linked to coping with cancer diagnoses have been demonstrated to increase the risk of sexual dysfunction (Brannigan, 2007).

As mentioned above, cancer treatments have the potential to impair the reproductive potential of oncologic patients. Since chemotherapy specifically suppresses the growth of rapidly proliferating cells, it is unsurprising that chemotherapy can damage the germinal epithelium as well. The degree to which reproductive ability is impaired by chemotherapy largely depends on the type of agent used, the drug dosage, and age of the patient. Alkylating agents such as cyclophosphamide have proven to be especially high risk for infertility. Impaired DNA function caused by these agents can result in genetic mutations in the germinal epithelium. While low doses of alkylating agents given to patients over a short period of time generally have reversible effects, higher doses and increased duration can lead to permanent damage (Brannigan, 2007).

Like chemotherapy, radiation therapy can damage the germinal epithelium. Because of the highly radiosensitive nature of the germ cells, fertility can be impacted by not only direct radiation but also scatter radiation from treatment of adjacent or nearby organs. Even just 2 Gy of radiation can damage spermatocytes and lead to irreversible azoospermia. Although many patients may regain spermatogenesis after treatment, some may experience a permanent reduction in sperm concentration or outright permanent and irreversible azoospermia (Brannigan, 2007).

Table 1 Medications that have potential detrimental effects on male fertility

<i>Medication/Drugs</i>	<i>Impact on fertility</i>
Diuretics, beta-blockers	Erectile dysfunction
Anti-psychotics	Lowered libido
Opioids	Hypogonadotropic hypogonadism
HAART	Impaired sperm motility and reduced ejaculate volume
Cannabis	Reduced testosterone levels
Tobacco	Damaged sperm DNA
Alcohol	Reduced androgen levels and impaired sperm parameters

References: [Brezina et al. \(2012\)](#), [Doulas and Douma \(2006\)](#), [Kulkarni et al. \(2014\)](#), [Niederberger \(2012\)](#), [Sigman et al. \(2009\)](#).

Medication and Drug Use

A summary of the impact of medications on male fertility can be found in [Table 1](#).

Antihypertensives

Erectile dysfunction from blood control medications is a common reason for patient nonadherence. Commonly used antihypertensive drugs such as diuretics and beta-blockers can result in erectile dysfunction, while ACE inhibitors and calcium antagonists less commonly have this side effect. Interestingly, some recent studies have shown that angiotensin II receptor blockers (ARBs) might have beneficial effects on reproduction as angiotensin II can contribute to the pathogenesis of erectile dysfunction ([Doulas and Douma, 2006](#)).

Antipsychotics

Antipsychotic drugs can reduce reproductive potential through several mechanisms. Dopamine plays a crucial role in maintaining libido, and most antipsychotic drugs function as dopamine antagonists, which can result in lower libido. Antipsychotic drugs can also elevate levels of prolactin which can lead to reduced sex drive in some patients. Additionally, studies have also shown that SSRIs specifically can cause anorgasmia and delayed or absent ejaculation in some patients ([Brezina et al., 2012](#)).

Opioids

Reduced release of LH and lowered levels of testosterone can result from opioid use, leading to hypogonadotropic hypogonadism. In addition, research has established that some endogenous opioid receptors reside in the testis, suggesting that opioids can impact spermatogenesis directly, although the mechanisms need further clarification. Discontinuation of opioid use typically leads to normalization of androgen levels ([Niederberger, 2012](#)).

Antiretrovirals

Numerous studies have found that highly active antiretroviral therapy (HAART) can result in impaired sperm motility, reduced ejaculate volume, abnormal sperm morphology, and other detrimental effects on mechanisms crucial for oocyte fertilization. Fortunately, despite these findings, most patients undergoing HAART often have preserved fertility ([Brezina et al., 2012](#)).

Occupational and Lifestyle Exposures

Recreational Drugs

Cannabis, tobacco, and alcohol use have all been shown to have negative repercussions for male fertility. Marijuana results in reduced testosterone levels in plasma proportional to the dose and duration of cannabis used. Cigarette smoking can impact the male reproductive system by inducing oxidative stress on semen with resultant damage to sperm DNA and reduction in sperm motility. Chronic alcohol use affects reproductive health by worsening sperm parameters and by reducing androgen levels ([Kulkarni et al., 2014](#)).

Heat

Scrotal temperature is regulated at 2–4 °C below body temperature primarily through its location outside of the body cavity and the countercurrent heat exchange produced by vasculature to and from the testes. The adverse effects of heat on the quality and output of sperm have been well documented, but the temperature at which thermal toxicity leads to infertility remains unclear. Studied sources of increased scrotal temperature range from clothes to body posture to laptop usage ([Thonneau et al., 1998](#)).

Pesticides and Insecticides

Research suggests that pesticides can impair male reproductive health. Dieldrin has been observed to cause defects in Leydig cell function, and both carbaryl and chlorpyrifos have been shown to damage DNA in the reproductive system. Even though counseling patients to consume local seems to be an intuitive solution to avoid the reproductive detriments of pesticides, one study actually found lower testosterone and LH levels as well as lower sperm concentration and aberrant sperm morphology in men who ate locally grown produce (Niederberger, 2012).

Pollution

A meta-analysis conducted in 2015 determined that air pollution has a deleterious impact on sperm motility, but not on other sperm parameters. Episodic exposure to high levels of air pollution has been shown to be associated with DNA fragmentation in sperm. Other studies have also linked air pollution to higher rates of miscarriage and lower rates of pregnancy (Deng et al., 2016).

Past Surgical History

A spectrum of surgical procedures including bladder neck, prostate, pelvic, and retroperitoneal surgery can result in ejaculatory dysfunction. Patients who experience retrograde ejaculation after surgery present with low-volume ejaculates and copious sperm in post-ejaculate urine. Treatment options include sympathomimetic drugs, electroejaculation, and recovery of sperm from postejaculatory urine or through surgical retrieval (Sigman et al., 2009).

Surgical repair of hydroceles and hernias in childhood can compromise fertility as well via obstruction of the vas deferens. Use of a surgical mesh during hernia repair can result in inflammation that can cause vasal obstruction. Other childhood procedures previously associated with male infertility include urethral valve ablation and bladder neck repair (Niederberger, 2012).

Immunologic Male Subfertility

Robert E Brannigan and Isaac Lam, Northwestern University, Feinberg School of Medicine, Chicago, IL, United States

Introduction

For about a century, sperm's potential to generate an immune response has been well recognized. In 1954, Rumke discovered the existence of anti-sperm antibodies and hypothesized that the antibodies may play a role in anomalous semen parameters and infertility (Meinertz, 1992). Since then, the knowledge base on the immune system's role in infertility has grown dramatically, but substantial gaps in understanding still remain. This article will first introduce the immune system for context, and then present an overview of the pathophysiology, diagnostics, and management of immune infertility.

The Immune System

Before delving into immunologic causes of male infertility, this section will give an overview of how the normal immune system functions in order to contextualize the rest of the article. The function of the normal immune system is to eliminate foreign material, or antigens. The body achieves this goal through two main mechanisms: innate immunity and adaptive immunity.

Innate Immunity

As the name implies, innate immunity refers to the part of the immune system that is programmed at birth. Cells involved in innate immunity include neutrophils, macrophages, and natural killer cells. Innate immunity reacts quickly and non-specifically to foreign antigens, taking only minutes to hours**** to mount a response. Innate immune cells use toll-like receptors (TLRs) to identify pathogen-associated molecular patterns (PAMPs) that commonly present on antigens such as the bacteria flagella or virus coats. Phagocytic cells such as macrophages and neutrophils then proceed to engulf and digest the identified antigens (Alberts, 2015).

Adaptive Immunity

Unlike innate immunity, adaptive immunity is highly specific to the invading pathogen. Antigen presenting cells (APCs) phagocytize the pathogen, then present antigens on type II major histocompatibility (MHC) proteins to T cells. When activated, the T cells either become cytotoxic T cells that destroy pathogens directly, or T helper cells that activate B-cells to produce antibodies. The released antibodies then attach to the pathogen and eliminate it through various mechanisms ranging from mast cell response to phagocytosis (Alberts, 2015).

Testicular Immunology

Because tolerance to self-antigens occurs during embryologic development and spermatogenesis does not begin until puberty, the immune system views sperm as foreign bodies. In order to prevent an autoimmune response, the testes are designed to be immunologically privileged, that is, immune reactions within the testes tend to be diminished relative to the same reactions that occur in other organ systems. Macrophages and lymphocytes are localized between seminiferous tubules but not within them, indicating that there is a blood-testis barrier that exists to create this distinction between the testicular immune system and the immune system of the rest of the body. This barrier is composed of two parts: the mechanical barrier and functional barrier (Walsh & Turek, 2009).

Mechanical Barrier

Sertoli cells found in the seminiferous tubules that primarily assist in spermatogenesis contribute to the mechanical barrier. Tight junctions, adherens junctions and gap junctions between Sertoli cells limit the migration of lymphocytes and large molecules such as immunoglobins. However, Sertoli cells alone are insufficient to maintain the blood-testis barrier as the density of junctions varies throughout the reproductive tract. For instance, the low density of junctions in the ductuli efferentes results in openings that allow entry of large molecules. Thus, a functional barrier is needed to complement the mechanical barrier (Cheng and Mruk, 2012).

Functional Barrier

The functional barrier is comprised of several mechanisms that down-regulate humoral and cell-mediated immunity. The vasculature of the seminiferous tubules assists with immunosuppression by ensuring lymphocytes do not accumulate in vulnerable portions of the germinal epithelium. Vulnerable regions of the germinal epithelium also house large numbers of T suppressor cells

that inhibit effector T cells and help produce immune tolerance at anatomically weak points of the seminiferous tubules. In addition, anomalies in human leukocyte antigen (HLA) proteins and sperm antigen-HLA associations may cause defective presentation of sperm antigens to lymphocytes, further contributing to the functional barrier (Cheng and Mruk, 2012).

Immunologic Infertility Mechanisms

Sperm Antigenicity

Most cases of germ line autoimmunity fall into one of two categories: testis-specific or anti-spermatogenic. In testis-specific autoimmunity, antigens induce a generalized immune response to the entire testicular organ leading to orchitis. The most common example of this phenomenon is mumps orchitis, a prevalent complication in post-pubertal men affected by mumps. The damage inflicted on testicular glands by the virus can cause inflammation of the parenchyma, interstitial lymphocyte infiltration, and seminiferous tubule separation. In the presence of these repercussions, mumps orchitis can lead to subfertility, including oligospermia, azoospermia, asthenospermia, and other defects. Although orchitis is not specific to the germinal epithelium, the general inflammation caused by orchitis often results in damage to epithelial and interstitial structures (Masarani et al., 2006).

In anti-spermatogenic autoimmunity, the immune response is specifically directed to the germinal epithelium. The resultant destruction of germ cell leads to a decline in spermatogenesis. A variety of sperm auto-antigens have been established using monoclonal antibody techniques. For instance, a sperm plasma membrane protein known as antigen 1 (FA-1) has been identified as an auto-antigen that regulates the interaction of sperm with zona pellucida, a glycoprotein layer surrounding oocytes. While antibodies against FA-1 do not impact sperm motility, their effects on sperm-zona pellucida interactions can still cause infertility (Coonrod et al., 1994).

Unfortunately, there are numerous limitations to the study of sperm antigenicity. A significant amount of current knowledge on sperm antigenicity stems from animal studies, which may not fully translate to human sperm antigenicity. In addition, sperm antigenicity is a highly dynamic phenomenon. At different stages of its maturity, sperm expresses a different set of antigens as it gain and loses antigens throughout development on the germinal epithelium. Lastly, cross-reactivity can be a confounding factor as well, as antibodies can bind to different molecules that share similar physical traits (Walsh and Turek, 2009).

Antibody-Mediated Sperm Autoimmunity

Although the immune system's ability to produce antibodies against sperm has been observed for a century, the exact clinical implications anti-sperm antibodies (ASA) have for male infertility remains uncertain. More than one out of ten males being evaluated for infertility have ASA, whether in the serum, seminal plasma, or bound to sperm (Turek and Lipshultz, 1994). Associations have been made between ASA and various conditions that result in the breach of the blood-testis barrier, but no causal link between ASA and infertility has been established. Some of these conditions include biopsy, vasectomy, testicular trauma, and other surgical procedures (Haas, 1987).

There are five different types of antibodies produced by the adaptive immune system including IgA, IgD, IgE, IgG, and IgM. Of the five only IgA, IgG, and IgM have demonstrated an ability to target sperm. IgMs have a large pentameric structure that restricts their ability to transudate to the seminal fluid, limiting the effects of IgM on infertility. IgA can be found in seminal fluid but typically does not present in the serum, and most IgGs in the seminal fluid are different from the IgGs in the serum. These two findings suggest that IgAs and IgGs that present in the testes are produced via local antigen inoculation and not systemic antigen inoculation (Haas et al., 1983; Uehling, 1971).

Antibodies may impair male fertility through various mechanisms. For instance, IgA bound to sperm has been shown to reduce sperm motility in the cervical mucus by binding to receptors in the mucus as well as causing agglutination of sperm. Female anti-sperm antibodies can impair the ability of sperm to penetrate the cervical mucus as well, quickly immobilizing sperm cells. Alternatively, antibodies can negatively impact fertility by binding to sperm and subsequently allowing phagocytosis or complement fixation of the sperm cells (McLachlan, 2002). Even if the sperm is not phagocytized or fixed by complement, the steric transformation of sperm caused by opsonization can interfere with sperm and egg interaction, as exemplified by the antibodies against FA-1 described earlier in this article. Some evidence even suggests that antisperm antibodies can lead to spontaneous abortions. In one study, zygotes derived from human sperm and animal oocytes expressed sperm-derived antigens shortly after fertilization, antigens that may leave the zygote vulnerable to opsonization (O'Rand, 1977).

Cell-Mediated Sperm Autoimmunity

In many cases of infertility, absence of antisperm antibodies suggests that cell-mediated autoimmune responses can be responsible for infertility as well. In spermatic cord torsion, necrosis and ischemia in the testis lead to release of significant amounts of sperm antigen. Despite this exposure to inoculum, the immune system does not produce significant levels of ASA in response, but a substantial amount of immune cell infiltration and inflammatory mediator release can be observed (Anderson et al., 1992). Studies have also demonstrated associations of elevated seminal white blood cell levels with abnormal semen parameters and impaired oocyte penetration (Anderson, 1990). However, not enough evidence exists to establish pyospermia as a cause of autoimmunity.

Cytokines produced by immune cells may play a role in infertility as well. Animal studies have demonstrated that sperm motility can be negatively impacted when the sperm is exposed to tumor necrosis factor and interferon gamma (Hill et al., 1987). However, evaluating the precise levels of cytokines in seminal fluid has proven to be difficult as prolific amounts of enzymes in seminal plasma quickly degrade the cytokines.

Immunologic Infertility Diagnostics

Antibody-Mediated Immunity

While there is no classic clinical vignette for antibody-mediated infertility, there are particular circumstances in which physicians should consider performing an ASA assay. These include sperm agglutination without infection, reduced sperm motility with a history of testis surgery or trauma, sperm shaking during sperm-cervical mucus contact testing, increased leukocyte levels, impaired mucus penetration on postcoital testing, and idiopathic infertility. When taking the history of the patient, the physician should ask about risk factors that would predispose the patient to antibody-mediated infertility, as well as attempt to rule out other causes before performing an ASA assay (Walsh and Turek, 2009).

The two most common tests used for ASA testing are the immunobead test (IBT) and the mixed agglutination reaction (MAR). The IBT functions by incubating fresh motile sperm with beads coated with antibodies against human immunoglobulins. Analysis of the test can determine the type of immunoglobulin bound to sperm, percentage of sperm with bound antibodies, and the location on sperm at which antibodies are present. Typically the threshold of significance is set to greater than 50% binding, although location of binding seems to play a role as well, for example, antibodies bound to the head of sperm have more significance than those bound to the tail. The MAR method uses a similar concept to the IBT. Fresh sperm is first incubated with beads or sheep erythrocytes labeled with human immunoglobulin. Then, anti-human immunoglobulins are added to the mixture. Results from IBT and MAR usually correspond fairly well. Other less commonly used methods include immobilization enzyme-linked immunosorbent assays (ELISA) and flow cytometry (McLachlan, 2002).

Cell-Mediated Immunity

Just as cell-mediated sperm autoimmunity is not as well understood as its antibody-mediated counterpart, diagnostics for cell-mediated immunity is relatively limited compared to testing for anti-sperm antibodies. The leukocyte migration inhibition factor (LMIF) assay, for example, can be used to measure sperm-leukocyte interaction***. Leukocytes are extracted from the serum of either partner and combined with sperm. The migration of leukocytes through a gel is then observed, with delayed migration indicating substantial sperm-leukocyte reaction. When applied to men with normal semen parameters, all assay results were negative. When applied to asthenospermic and oligoasthenospermic men, about half and one quarter had positive assay results respectively (Dimitrov et al., 1994). While the sensitivity of the assay may not be ideal, more accurate assays for evaluating cell-mediated immune infertility will likely develop as knowledge on sperm autoimmunity expands.

Immunologic Infertility Treatment

Corticosteroids

Immunosuppressive drugs reduce immune activity by dampening both the humoral and cellular components of the immune system. Thus far, however, few studies have been done on the impact of corticosteroids on immune fertility. One study conducted over 3 months found no significant difference between the control and experimental groups, whereas another study performed over 9 months indicated that treating patients with corticosteroids may lead to higher pregnancy rates (Hendry et al., 1990; Haas and Manganiello, 1987). This may suggest that long-term use of immunosuppressive drugs can contribute to improved fertility.

Intrauterine Insemination (IUI)

As described earlier in the article, sperm opsonized by antibodies often have a reduced ability to penetrate the cervical mucus. In intrauterine insemination, a small catheter is used to place the sperm in the uterus, bypassing the cervical mucus. Because opsonized sperm have a shorter lifespan, the timing of the procedure plays a key role in the success of IUI. Sperm washing prior to insemination also increases the chance of success by reducing the amount of antibodies bound to sperm. While there have been various studies suggesting the effectiveness of IUI for immune infertility treatment, no randomized controlled trials have been conducted on this issue thus far (Walsh and Turek, 2009).

In-Vitro Fertilization (IVF)

In IVF, both sperm and egg are harvested and the process of fertilization is performed in the laboratory. The new embryo is then placed into the uterus. Unfortunately, use of IVF as treatment for immune infertility seems to have a lower success rate compared to using IVF for other indications. Interestingly, studies observing the effects of immunoglobulin bound to sperm on IVF suggest that

the procedure has high success rates when sperm is only bound to either IgA or IgG, but these rates drop significantly when bound to both. In certain cases that IVF is not a viable option for overcoming immune infertility, intracytoplasmic sperm injection (ICSI) can be utilized. An individual sperm is extracted, immobilized, and injected into the egg cytoplasm. This procedure can specifically help those with immune infertility achieve fertility by allowing the sperm to bypass both the zona pellucida and oocyte membrane, both of which can have defective interactions with sperm due to ASA interference. However, studies have shown that sperm with ASA bound still result in lower quality embryos after ICSI compared to their ASA free counterparts (Walsh & Turek, 2009).

Glossary

MAGI (male accessory gland infections) MAGI includes infections involving one or more of the following male genital organs or tracts: seminal vesicles, prostate, vas deferens, epididymis, testicles, urethra and Cowper glands.

Nomenclature

DFA Direct fluorescent antibody
EIA Enzyme immunoassay
FTA-ABS Fluorescent treponemal antibody-absorption test
GU Genitourinary
IFA Indirect fluorescent antibody
HCV Hepatitis C virus
HBV Hepatitis B virus
HIV Human immunodeficiency virus
HPV Human papilloma virus
MAGI Male accessory gland infections
PCR Polymerase chain reaction
PFGE Pulsed-field gel electrophoresis
REA Restriction enzyme analysis
RPR Rapid plasma reagin
STD Sexual transmitted disease
U Urealyticum ureoplasma urealyticum
VDRL Venereal Research Disease Laboratory
URS Unheated serum reagin

Introduction

Reproductive tract inflammation and infection are a common cause of male infertility, with a prevalence of 6%–10% on male infertile population. Infections can affect different sites of the male reproductive tract, such as testis, epididymis and the male accessory sex glands. Bacteria, viruses, fungi and parasites as well as inflammatory causes such as environment toxins, which are able to interfere in the human male's reproduction ([Table 1](#)). Most of the affected men are asymptomatic.

The following mechanism has been proposed to produce infertility ([Krause, 2008](#)).

Obstruction of the Reproductive Tract

The inflammation produced after a bacterial infection of the genital tract, can produce scars and consequently a stricture of the reproductive ducts. It is important to start a suitable antibiotic treatment to avoid these complications.

Stenosis of the epididymal duct may occur in the course of epididymitis, leading to a reduction of sperm count and finally to azoospermia. Urethritis can cause urethral scarring and stricture formation, leading to a decreased ejaculation volume and to a reduced fertility.

Impairment of Spermatogenesis

Epididymitis may frequently be associated with orchitis. Testicular tissue is very sensible to inflammatory changes, which can cause disturbances in a temporary or a definitive sperm production.

Table 1 Infections and inflammatory conditions related to male infertility*Infections diseases associated with infertility*

Bacteria	<i>Neisseria gonorrhoeae</i> <i>Chlamydia trachomatis</i> <i>Mycoplasma</i> <i>Ureoplasma</i> Non-STD bacteria like <i>E. coli</i> , <i>Enterococcus fecalis</i> , group B, <i>Streptococcus</i> and <i>Staphylococcus aureus</i>
Yeast	<i>Candida albicans</i>
Parasites	<i>Trichomonas vaginalis</i>
Virus	Hepatitis B virus Hepatitis C virus Human immunodeficiency virus Human papilloma virus Herpes virus
Inflammatory conditions associated with infertility	Prostatitis Epididymitis Urethritis Obesity and metabolic syndrome Chronic disease

Impairment of Sperm Function

MAGI (Male Accessory Gland Infections) can directly affect the spermatozoa and deteriorate sperm parameters.

Dysfunction of the Male Accessory Glands

The inflammation impairs the secretory function of the male accessory glands. The seminal concentrations of citric acid, L-carnitine, fructose, zinc concentration and alpha-glutamyltransferase are decreased in MAGI (Cooper et al., 1990).

Antisperm Antibodies

The presence of sperm antibodies reduces male infertility. They are usually formed after a disruption of the blood–testis barrier, in situations like testicular torsion, vasectomy or trauma. The role of antisperm antibodies in inflammation/infection processes is unclear (Marconi et al., 2009), but may be related to the chronicity of the inflammatory process (Bachir and Jarvi, 2014).

Pathogens Involved in Genital Tract Infection

Bacteria, viruses, fungi and parasites are able to interfere in male reproductive biology.

Bacteria***Neisseria gonorrhoeae***

This gram negative diplococci is a very common STD (sexual transmitted disease) in men. *N. gonorrhoeae* causes urethritis, prostatitis and less frequent epididymitis. The organism rarely has haematogenous spread. Gonorrhoeic urethritis is associated with urethral strictures that can decrease ejaculate volume. Men who developed epididymo orchitis, showed a strong impairment of testicular function 2 years later (Osegbe, 1991).

Chlamydia trachomatis

This organism is an intracellularly living bacterium. It is also one of the most common worldwide STD. The most common affections in males are urethritis and epididymitis, but they can be asymptomatic (Krause, 2008). It may impair male infertility

by causing scarring and obstruction along the male reproductive tract, and it can also cause sperm cell apoptosis (Wan et al., 2003).

Its role in infertility in asymptomatic individuals is not yet definitely determined (Ahmadi et al., 2016).

Mycoplasma and ureaplasma

Genital infections by *Mycoplasma hominis*, *Mycoplasma genitalium* and *Ureaplasma urealyticum* have been evaluated as causes of male infertility.

Ureaplasma urealyticum is the most common pathogen isolated from the genital tract of men with infertility. Studies have shown that men with infertility have higher frequencies of *U. urealyticum* detection in the semen than fertile men. Progressive motility and vitality are significantly lower in men infected by *U. urealyticum* positive than noninfected infertile men.

The presence of *Mycoplasma hominis* is also associated with a low total motility and with a total motile sperm count (Lee et al., 2013). *Mycoplasma genital* seems not to be associated with infertility (Huang et al., 2015).

Non STD bacteria

Non-STD bacteria like *E. coli*, *Enterococcus faecalis*, group B, *Streptococcus* and *Staphylococcus aureus* can cause male infertility. *E. coli* adheres to spermatozoa causing sperm agglutination (Diemer et al., 2000). The prevalence of bacteriospermia in men with infertility is approximately 15%. Bacteriospermia does not usually affect sperm cell parameters, but it is associated with a higher sperm DNA fragmentation (Domes et al., 2012).

Yeast

In vitro studies *Candida albicans* infection decreases sperm motility (Tuttle et al., 1977) and prevents fertilization after IVF (in vitro fertilization) and ICSI (intracytoplasmic sperm injection). The association of *Candida albicans* and male infertility is unclear, but it can possibly have a negative effect.

Parasites

Trichomonas vaginalis is the most important parasite involved in male infertility. It's a flagellated parasite often found as an occult resident of the genital tract of sexually active women and men. It binds to sperm head and flagella leading to a reduction of sperm motility and it increases agglutination (Benchimol et al., 2008).

Viruses

Besides the risk of horizontal or vertical transmission, viruses can negatively affect sperm parameters, fertilization and abortion rate (Garolla et al., 2013). It's known that chronic infection with HBV (hepatitis B virus) and HCV (hepatitis C virus) are associated with a deterioration of sperm parameters (count, motility and morphology) (Lorusso et al., 2010). An increase in oxidative stress has been observed, resulting in a major range of apoptosis and necrosis, versus noninfected patients (Moretti et al., 2008).

HIV (human immunodeficiency virus) impaired significantly sperm parameters. The sperm damage is correlated with CD4 count. Undetectable viral load improve the outcome of IUI/sperm washing in HIV(+) men (Nicolopoulos et al., 2004).

The influence on fertility of other viruses like human papilloma virus (HPV) and herpes virus is unknown. Hybridization technology have demonstrated in situ that HPV attaches to the equatorial region of the sperm head in semen (Schillaci et al., 2013), but the implication on male infertility is unclear (Yang et al., 2013; Luttmer et al., 2016).

Inflammatory Conditions Resulting in Male Infertility

Inflammation is the result of injury and tissue damage. When it has occurred, the presence of inflammatory cells (macrophages and lymphocytes) and proinflammatory cytokines affects sperm production (Azenabor et al., 2015). Many inflammatory noninfectious diseases can affect male infertility.

Prostatitis

Chronic prostatitis is the most common urologic condition in male patients younger than 50 years. Men with symptomatic noninfectious prostatitis has a reduced sperm motility and morphology (Leib et al., 1994; Pasqualotto et al., 2000).

Epididymitis

Acute epididymitis usually produces a temporary deterioration in sperm parameters in most of patients. Semen quality usually recovers after 6 months. Even though, azoospermia has been observed in some patients that can last more than 2 years from diagnosis (Bachir and Jarvi, 2014).

Orchitis

Most cases of orchitis are produced by infectious diseases (bacteria and virus), but it can also be produced by noninfectious causes, for example in autoimmune orchitis. Chronic inflammation of the testis may lead to impaired spermatogenesis and may reduce fertility.

Obesity and Metabolic Syndrome

Sperm parameters are impaired in obese men, specially sperm concentration. White adipose tissue is responsible for aromatase activity, that converts testosterone to estrogen. Obese men have decreased levels of testosterone and increased levels of estradiol. They also have increased oxidative stress (Katib, 2015).

Other Diseases Associated With Inflammatory Infertility

Spermatogenesis and testicular tissue are very sensible to inflammation and oxidative stress. Spermatozoa have limited levels of antioxidant defense and a limited ability of DNA-damage detection and repair mechanism (Bisht et al., 2017). Patients diagnosed of systemic diseases have increased levels of reactive oxygen species (ROS). Approximately 64% of people with cancer have a reduction in semen quality (Van Casteren et al., 2010).

Chronic diseases as inflammatory bowel disease are associated with infertility (Palomba et al., 2014).

Evaluation and Diagnosis of Genital Tract Infections

The clinical manifestation of the different infectious and inflammatories conditions determines the location in the genitourinary tract. In Table 2, there is the summary of the symptoms and diagnosis studies. Most STD can be diagnosed isolating pathogen in urethral exudate. Currently, semen culture is not recommended as a routine diagnostic test due to the high probability of urethra or skin contamination (Bachir and Jarvi, 2014). However, semen aerobic cultures can be considered in those men with high levels of sperm DNA fragmentation and antibiotic therapy can be provided to all of the patients with positive culture.

In chronic prostatitis, it is very difficult to find the microorganism with regular urine culture. In these cases, urine culture after prostatic massage according to Stamey technic can provide more specific microbiological information (Sibert et al., 1996).

When there is a high suspicion of genital infection and urinary cultures are negative, the tissue biopsy culture can render information. However, biopsies are contraindicated in acute epididymitis or orchiepididymitis (Schagdarsurengin et al., 2016).

Treatment

When genitourinary and reproductive tract infection is suspected, it is important to start a suitable antibiotic treatment immediately to avoid complications. Even though bacterial clearance by antibiotic therapy eradicates the pathogen and relieves pain symptoms, impaired semen parameters persist in 40%–80% of patients for up to 3 months and in 20% of cases beyond (Schagdarsurengin et al., 2016).

The most commonly used treatment for the *Neisseria gonorrhoeae* infection is the beta-lactamic for high sensibility. In cases of penicillin allergy, the fluoroquinolone is an option.

Tetracyclines are the first option for *Chlamydia trachomatis* infection. In the cases of *Treponema pallidum* penicillin is the election. For *Mycoplasma* and *Ureaplasma urealyticum* usually the Macrolides are the choice. For the Herpes virus the election is antivirals as Acyclovir oral or topic. In Table 2 the treatments are summarize.

In cases of obesity and metabolic syndrome, loss of weight and control of glycemic levels are recommended. It is important to control all the chronic conditions.

Table 2 Diagnosis and treatment of infections associated to male infertility

Agents	Clinics GU tract	Diagnosis	Treatment	Screening	Effect on male fertility
<i>Neisseria gonorrhoeae</i>	Urethritis, epididymitis, orchitis, infertility, disseminated gonococcal infection	Isolation pathogen in urethral exudate, detection of antigen or nucleic acid, DFA, EIA	• Ceftriaxon 250 mg IM q.d. • Azythromycin 1 g q.d. • Metronidazol 250 mg t.i.d./24 h • Fluoroquinolone q.d.	In specific populations with higher prevalence of <i>N. gonorrhoeae</i>	• Causes of strictures on the difference ducts (urethra, epididymo-orchitis)
<i>Chlamydia trachomatis</i>	Urethritis, epididymitis, orchitis, Reiter's syndrome, lymphogranuloma venerium, groin ulcers	Isolation pathogen (tissue culture or urethral exudate), direct detection of antigen (DFA, fluorescent tagged monoclonal antibodies), nucleic acid amplification (PCR), EIA	- Azythromycin 1 g q.d. - Doxycycline 100 mg b.i.d /7d. - Erythromycin - Fluoroquinolone	In specific populations with higher prevalence of <i>C. trachomatis</i>	• May impair sperm motility
<i>Treponema pallidum</i>	Primary ulcer with hard edges and local no pain adenopathy, condylomata lata	Dark-field microscopy, DFA PCR, EIA, FTA-ABS, VDRL, RPR, USR.	• Benzathine penicillin 2,4 mill IM q.d. • Doxycycline 100 mg b.i.d /14d.	In specific populations with higher prevalence of <i>T. pallidum</i>	• Possible attach to sperm cells. • Gummatous testicular lesions • Co-factor for transmission of HIV
<i>Mycoplasma genitalium</i>	Urethritis, urethral discharge	Isolation pathogen in urethral exudate, Culture, PCR, IFA	• Macrolides • Tetracyclines • Fluoroquinolone	Screening not suggested	
<i>Ureaplasma urealyticum</i> <i>Mycoplasma hominis</i> <i>Gardnerella vaginalis</i>	Urethritis, urethral discharge	Isolation pathogen in urethral exudate, PCR, IFA Dense aggregates of gram-negative bacilli on desquamated epithelial cells (Clue cells)	• Azythromycin 1 g q.d. • Doxycycline 100 mg b.i.d /7d. • Metronidazol 250 mg t.i.d./7 h	Screening not suggested	• Possible attach to sperm cells • May alter sperm parameters
HSV-2, HSV-1	Anogenital vesicular lesions and ulcer lesions	Zanck test, DFA, PCR, EIA, direct DNA detection	• Aciclovir 400 mg t.i.p/10d • Valaciclovir 500 mg b.i.p/10d	Screening not suggested	• May alter sperm parameters
HPV	Genital and anal warts; carcinoma of the penis	Pap smear, PCR, hybrid capture HPV DNA	• Famciclovir 250 mg t.i.p/10d • Imiquimod cream • Podophylin cream • Surgery	Screening not suggested	• May alter sperm parameters
<i>Trichomonas vaginalis</i>	Asymptomatic	Direct observation in the microscopy, demonstration of nucleic acid	• Metronidazol 2 g q.d.	Screening not suggested	• Binds to sperm head and flagella
<i>Candida albicans</i>	White superficial penis and foreskin	Culture, direct observation, PFGE, PCR	- Fluconazole 150 mg q.d. - itraconazole o clotrimazole cream	Screening not suggested	• In vitro: inhibitory effect in human sperm motility

GU, genitourinary; IFA, indirect fluorescent antibody; DFA, direct fluorescent antibody; EIA, enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody-absorption test; PCR, polymerase chain reaction; REA, restriction enzyme analysis; PFGE, pulsed-field gel electrophoresis; VDRL, Venereal Research Disease Laboratory; RPR, rapid plasma reagin; URS, unheated serum reagin.

Conclusion

Infectious and inflammatory diseases of the genital tract are an important cause of infertility. A prompt diagnose and correct treatment can prevent further genitourinary complications and infertility.

Varicocele: Evaluation and Pathophysiology

Nikita Abhyankar and Samuel Ohlander, University of Illinois-Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

A varicocele is an abnormal dilation of the pampiniform plexus of veins in the scrotum, similar to the dilation of veins in the leg known as varicose veins (**Fig. 1**). Varicoceles are a common finding, occurring in 15% of all men. The prevalence of varicocele in primary infertility (defined as inability to conceive a first child after 1 year of unprotected intercourse) is 19%–41% and up to 80% of men with secondary infertility (defined as inability to conceive after unprotected intercourse for a year in an individual who has previously had a biological child) (**Witt and Lipshultz, 1993**). The relationship between infertility and varicocele is still incompletely understood, but current knowledge will be explored throughout this article.

Epidemiology

The prevalence of varicocele appears to increase with age during the childhood years. Researchers found <1% in boys aged 2–10 had varicoceles, 7.8% in boys aged 11–14 years and 14.1% in boys aged 15–19 years (**Akbay et al., 2000**). Other studies have similarly shown a rising prevalence with age in adult men with an increase of approximately 10% with every decade of life. This suggests a mechanism of venous incompetence worsening with age. There is also some indication of a higher incidence of varicose veins in the lower extremities of men with varicocele, perhaps suggesting a similar pathogenesis. The majority of varicoceles occur on the left side; however, around 50% of men have bilateral varicoceles (**Abdulmaaboud et al., 1998**). Isolated right sided varicoceles are less common (<5%) and should prompt further evaluation.

Somewhat counterintuitively, obesity has been found to negatively correlate with the presence of varicoceles. One theory for the reason is the increased difficulty of physical examination to identify the varicocele in obese individuals. Alternatively, common thought suggests that the increased adipose tissue in individuals with higher BMIs reduces potential compression of the renal vein since adipose has a lower density, thus, protecting against obstructed flow and venous congestion.

Several studies have shown that varicoceles do have a hereditary component. **Raman et al. (2005)** showed an eight times higher incidence in men with a first degree relative with a varicocele. While the correlation has been observed, the genetic etiology for this hereditary pattern has not yet been elucidated.

Other described risk factors for varicocele include congenital incompetence of valves in the spermatic veins or an acquired incompetence of the spermatic veins due to external compression of the gonadal veins in the retroperitoneum.

Etiology

Several theories exist for the cause of varicocele in men; however, there is not yet consensus on the exact cause. Absence of venous valves has been postulated as a contributing factor. The suggested mechanism for this is that absent valves leads to a higher back pressure in the gonadal vein, venous pooling, increased testicular temperature, accumulation of reactive oxidative species and, therefore, suboptimal spermatogenesis. It has been shown that in men overall, valves are absent in the left gonadal vein in 40% compared to 23% in the right gonadal vein (**Ahlberg et al., 1966**). Varicoceles are significantly more common on the left side, aligning with the valve theory. However, varicoceles can still occur in patients with competent valves.

Another theory for the etiology of varicoceles and the reason for left sided preponderance is anatomical. The left gonadal vein has a right-angle insertion into the left renal vein compared to the more oblique insertion of the right gonadal vein into the inferior vena

Fig. 1 Varicocele.

cava. In addition, the left renal vein has a higher pressure than the IVC, increasing back pressure and a higher venous tension in the left gonadal vein as compared to the right. This higher venous tension is thought to lead to venous pooling.

External compression of the gonadal veins can also contribute to varicocele formation. This compression may be due to a retroperitoneal mass. Patients with a right sided varicocele, or acute development of a varicocele should be evaluated for a retroperitoneal mass given the rarity of isolated right sided varicocele and their typical chronic development. Other causes of external compression of the gonadal vein include the “nutcracker syndrome.” Classically, anterior nutcracker syndrome is when the left renal vein is compressed between the aorta and the superior mesenteric artery (SMA) increasing the pressure in the left gonadal vein. This is thought to occur because the SMA branches from the aorta at an angle less than the usual 90 degree, resulting in compression of the left renal vein. A variant known as posterior nutcracker syndrome refers to when the left renal vein is retroaortic and is compressed between the aorta and vertebra. Nutcracker syndrome is believed to occur more commonly in patients with a lower BMI. Nutcracker syndrome, however, remains a rare cause of varicocele.

Varicocele—Evaluation

The American Society of Reproductive Medicine (ASRM) and American Urological Association (AUA) produced a joint report on best practice for varicocele in 2001. This report recommended evaluation of a male with a varicocele to include a history, physical examination and two semen analyses. This was further supported, though briefly, by the AUA’s best practice policy, optimal evaluation of the infertile male (Jarow et al., 2011). The lack of formal guidelines on management is attributed to the lack of well-designed studies and inconsistency of data on the impact of varicoceles on fertility and treatment outcomes.

Varicoceles are not usually symptomatic and are often discovered at the time of infertility evaluation. Symptoms that can occur include heaviness, dull aching pain, and warmth. These symptoms are usually worse with strenuous activity and improve on recumbency.

Physical examination remains the gold standard for diagnosis of varicocele. Examination is typically performed in a warm room in the supine position and then the standing position with and without Valsalva. Examination findings of palpable veins within the scrotal sac are classically described as a “bag of worms” (Fig. 1). Testicular atrophy, either unilateral or bilateral, can also occur due to varicocele. Varicoceles are graded according to the physical examination findings (Table 1).

The majority of varicoceles occur on the left side; however, around 50% of men have bilateral varicoceles. Isolated right sided varicoceles are less common (<5%) and should prompt evaluation as they may be found with situs inversus or retroperitoneal masses (Masson and Brannigan, 2014). Only palpable varicoceles have been associated with infertility, hence the AUA best practice statement recommended no ancillary diagnostic testing to identify subclinical varicocele (Jarow et al., 2011).

Two semen analyses should be obtained due to variability of semen parameters over time. It is recommended that the man abstains from ejaculation for 2–3 days prior to acquisition of the semen specimen. Overall men with varicoceles have been shown to have a stress pattern with reduced sperm concentration (oligo-), poor motility (astheno-), and poor morphology (terato-) compared to men without varicocele (Agarwal et al., 2016). This is known as oligoastheno-teratozoospermia. However, while classically described, not all men with varicocele have these abnormalities.

Pathophysiology

Varicocele has a higher prevalence in men presenting with infertility than those without. There is a higher rate of varicocele in men with secondary infertility as compared to primary infertility, and this is thought to be suggestive of a progressive disease course which worsens with time or age (Akbar et al., 2000).

The cause of these effects on testicular function is incompletely understood since some men experience subfertility from varicocele, while others do not. There are several factors that are thought to contribute to male infertility in men with varicocele; heat stress, hypoxia, oxidative stress, hormonal abnormalities, and exogenous intoxicants (Sheehan et al., 2014).

Physiologic temperature in the testicle is lower than that of the rest of the body. This is believed to be due to heat dissipation as a result of countercurrent blood flow in the pampiniform plexus around the testicular artery (Dahl and Herrick, 1959). In men with varicoceles, dilation of the pampiniform plexus veins alters the physiology, by allowing venous congestion and pooling. Human

Table 1 Varicocele grading

<i>Subclinical</i>	<i>Not present clinically, abnormality only seen on ultrasound</i>
Grade 1	Only present clinically when man performs Valsalva maneuver
Grade 2	Easily palpable, not visible
Grade 3	Visible through scrotal skin, easily palpable

Dubin, L., and Amelar, R.D. (1970). Varicocele size and results of varicocelectomy in selected subfertile men with varicocele. *Fertility and sterility* 21(8), 606–609.

studies have demonstrated a higher intra-testicular temperature and scrotal temperature in those with a varicocele compared to unaffected men (Goldstein and Eid, 1989). The mechanism of impairment in function from this elevated temperature is thought to be due to enzymatic activity in the testicle being suboptimal at a higher temperature. These affected enzymes appear to be principally involved in DNA synthesis. Fujisawa et al. (1988) demonstrated that levels of enzymes involved in DNA synthesis, were lower in infertile men with varicoceles when compared to controls. In addition to DNA synthesis, other enzymes have been shown to have altered activity in men with varicocele, also thought to be associated with the increased temperature. Other key enzymes involved in protein folding, function and sperm motility have also been shown to be affected by varicocele. One of these enzymes is the heat shock protein (HSP). HSPs are molecular chaperones that function to protect against misfolding of proteins due to heat stress and mediate homeostasis of protein degradation and synthesis. HSPs allow cells to survive in conditions where they otherwise might not (Feder and Hofmann, 1999). Several studies have shown differences in expression of various HSPs in men with varicoceles when compared to controls (Lima et al., 2006). Lima et al. showed HSP2A had a lower expression in adolescents with varicoceles and oligozoospermia when compared to adolescents with varicoceles but normozoospermia, as well as adolescents without varicoceles. Suggesting a role of HSP2A in the pathophysiology of infertility in men with varicocele.

Testicular capillary pressure has been shown in animal studies to be particularly low and steady. Therefore, an increase in venous hydrostatic pressure due to varicocele formation can lead to stagnation of the capillary flow and hypoxic-ischemic changes in the testicular tissue. Increased expression of hypoxia inducible factor HIF1- α have been shown in the spermatic cord veins men with varicoceles (Lee et al., 2006). HIF1- α is a protein considered to be a key regulator of the response to hypoxia, thus implying some degree of hypoxia in testicles affected by varicocele. It has been shown that infertile men with varicocele have a higher HIF1- α expression, suggesting hypoxia as a contributing factor for infertility. The reason for the differences between men with varicocele who are fertile versus not fertile is unclear.

An excess of reactive oxidative species (ROS) is also thought to be involved in the pathogenesis of varicocele. ROS occur as a product of oxygen metabolism and have been found to be an important for intracellular homeostasis and for various aspects of sperm function (Griveau and Le Lannou, 1997). These sperm functions include capacitation (the penultimate step in sperm maturation which occurs postejaculation), acrosome reaction (a reaction which allows the sperm to penetrate the outside layer of the egg) and hyperactivation (higher amplitude of sperm motility to aid egg penetration) (Griveau and Le Lannou, 1997). Several studies exist which have shown a higher level of ROS or oxidative stress in men with varicoceles (Barbieri et al., 1999). This excess of ROS has been associated with a higher degree of DNA fragmentation. DNA fragmentation has been quantified as the DNA fragmentation index (DFI), which is the proportion of DNA which is damaged. A higher DFI has been associated with reduced sperm motility, higher spontaneous abortion rates and possibly a lower pregnancy rate with assisted reproductive technologies (Zhao et al., 2014). Thus, this higher level of ROS in men with varicocele may be contributing to the resultant subfertility.

There is some evidence that varicocele may also affect Leydig cell function. Leydig cells in the testes produce testosterone, keeping the microenvironment with a very high concentration for sperm generation. It has been postulated that the difference in temperature leads to alterations in testosterone production by Leydig cells in men with varicoceles, affecting spermatogenesis. An early animal study in which unilateral varicocele was induced in rats showed lower testosterone concentration in bilateral testes as well as a reduction in two of the enzymes required for testosterone production (Rajfer et al., 1987). Recent publications evaluating men following varicocele repair have shown a significant increase in serum testosterone levels in men with preoperative hypogonadism (Dabaja and Goldstein, 2016). There is some controversy, however, on whether varicocelectomy should be performed for treatment of age related hypogonadism. It has been speculated that in older men with long term varicocele, the testicle may not be able to recover functionality to produce normal levels of testosterone again. However, there is recent data to dispute this and suggest that even older men with hypogonadism can have improvements in testosterone levels with varicocelectomy (Dabaja and Goldstein, 2016).

Ultimately, while many hypotheses exist, the exact cause of subfertility in men with varicocele and why some men are affected while others are not, remains unclear.

Introduction

Men and women, because of their lifestyle, professional careers, late marriages and other factors, are delaying childbearing. In United States the birth rate in men older than 35 years has increased by 40% since 1980 (Alshahrani et al., 2014). Though maternal age has been widely investigated (Lansac, 1995), scarce information has been published about the role of paternal age in the conception progress and the potential consequences on the offspring. Advanced paternal age is believed to have a potential negative impact in fertilization rates, birth outcomes and childhood and adult health status (Table 1). Any man aged 40 years (y) or older at the time of conception is usually the age threshold considered for the definition of advanced paternal age. Investigate how paternal age may impair sperm and offspring development would help us to advice patients as well as to propose screening protocols to deliver healthy newborns (Conti and Eisenberg, 2016).

Semen Parameters

Modifications in semen parameters have been described as men grow older. Consensus exists about the fact of declination in volume, motility and normal morphology in men after 50. Kidd et al. analyzed 21 studies and stated declines ranging from 3% to 22% in semen volume, 3%–37% in motility and 4%–18% in normal morphology. Those data were reinforced by a meta-analysis published in 2015 underlining the decrease in semen volume, total sperm count, percent motility, percent progressive motility and percent normal sperm. The most controversial semen parameter is sperm concentration, which has been found to decrease with age in some studies and improves in some others (Plastira et al., 2007; Braham et al., 2011; Nijis et al., 2011).

Table 1 Pathologies and conditions with increased risk for the offspring of aged male

Achondroplasia	Centras Nervous System malignancies
Apert Syndrome	non-Hodgkin lymphoma
Crouzon Syndrome	Breast cancer
Pfeiffer Syndrome	Prostate Cancer
Klinefelter	Autism spectrum disorders
Syndrome	Schizophrenia
Leukemia	Bipolar disorder

The mechanisms to explain those changes in semen characteristics may be related to some anatomical structures. First, the seminal vesicle insufficiency could reduce semen volumen. Smooth muscular atrophy in the prostate as well as a decrease in water and protein content, may be responsible of the reduced semi volume and sperm motility (Kidd et al., 2001), which in addition might be altered by the inadequacy of the epididymal function with age.

Another situation that impairs semen parameters is the degeneration of the germinal epithelium status. Since Hendelsman et al. reported a decrease in testicular volume with age, another studies have proposed a difference in volumen of the 31% over 70 years when compared with men of 18–40 years (Handelsman and Staraj n.d.; Mahmoud et al. 2003). A reduction of Sertoli cell mass has been proposed to be responsible of the lower testicular volume in aged. In addition, thickening of basal membrane, narrowing and sclerosis of the tubular lumen, impaired blood supply and decreased in Leydig cells are other factors that contribute to explain the association of low testicular functions and age (Johnson et al. 1988).

Advanced paternal age may be a handicap to conceive because of sperm DNA damage, which relates with impaired fertility and abnormal embryo development, and with increased miscarriage rates. As much as an 88% is the estimated percentage of DNA damage is men between 60 and 80 years (Wyrobek et al., 2006). Several mechanisms have tried to explain how age may develop DNA damage proposing oxidate stress or inefficient apoptosis processes. Thus, DNA damage has been identified as predictor of low fertilization rates. Alshahrani et al. found a 24.4 $\pm$ 18.5% of sperm DNA damage in the group over 40 years of 472 non-azoospermic males seeking help for fertility issues, which was statistically significant when compared with the group under 40 years. (Alshahrani et al., 2014). Trying to clarify if the relationship between paternal age and DNA damage is independent of the relationship between paternal age and conventional semen parameters, Das et al. determined the DNA fragmentation index (DFI) in normozoospermic men under and over 40 years, and did so with another group of oligoasthenozoospermic men. In both groups the DFI of men over 40 years was significantly higher than in men under 40 years. Thus, in normozoospermia group, was around 15% over 40 years, and around 10% under 40 years (p 0.008). Another interesting finding of this author was the fact of the inverse correlation between percentage DFI with progressive sperm motility, supporting the idea that chromatin integrity and sperm motility are related (Das et al., 2013).

Natural Conception and Assisted Reproduction Techniques

Natural fecundity may be dependent on paternal age. 50% of couples succeed in conception within 3 months, reaching the 85% by the end of the first year (Bongaarts., 1975). Increasing male age is associated with significant decline in fertility reaching a fivefold longer time to pregnancy at age of 45 years (Hassan and Killick, 2003). Using time to conception to measure fecundity, Ford et al. determined an odds ratio for conception under 12 months of 0.51 for men over 40 years when compared to the group younger than 25 years (Ford et al., 2000). Another study concluded with 3287 couples that paternal age increase the time to pregnancy onset and conception difficulties when men were above 40 years (de La Rochebrochard and Thonneau, 2003). It has been proposed that advanced paternal age may modify time to conception, not only by biological issues, but because the reduced coital frequency also found in aging male. Defining spontaneous abortion as the death of fetus earlier than 20 weeks, and odds ratio os risk of having miscarriage increased to 1.80 in the group of men aged 40 to 64 years compared to 20 to 29 years and maintaining maternal age in the range from 20 to 29 years (de La Rochebrochard and Thonneau, 2003).

When the setting of assisted reproduction techniques (ART) is established, several publications, though no all of them, agree about the deleterious effect of paternal age. Robertshaw et al. found a 26% decrease in live birth rate with in vitro fertilization (IVF). When intrauterine insemination (IUI) is analyzed, when the male is over 35 years the pregnancy rate reduces by half (Robertshaw et al., 2014). A decline fertilization, blastocyst formation, implantation, and cryopreservation rates have been observed with advancing age. As well, in men with abnormal semen concentrations, pregnancy rates decrease 5% for each year of paternal age. This results were not that evident when adjusted to normozoospermic men. In contrast, Gallardo et al. found that increasing male age did not affect sperm characteristics or its ability to fertilize human eggs. Similarly, embryo development in vitro as well as implantation were not affected by age of the male when oocyte donor was restricted at 35 years or younger (Gallardo et al., 1996).

Hormones

Advanced age is associated with several hormonal changes that affect the hypothalamus-pituitary-gonadal axis (HPG), with the luteinizing hormone (LH) as a key participant in the regulation. LH alterations depend on the Leydig cell mass, sensitivity of the HPG to feedback inhibition, and decrease LH pulse amplitude. By the age of 75 years, bioavailable testosterone (bio-T) may be reduced by 50%. This bio-T has an important role binding to Sertoli cells maintaining essential intratesticular testosterone for spermatogenesis and preserving, thus, normal fertilization capability. In the same way, elevated follicle stimulating hormone (FSH) is usually found in male aging. Another hormone which is modified by age is sex hormone binding globulin (SHBG), that retains testosterone and make it inactive when bounded. SHBG increases with age explaining the disproportion between total serum testosterone and bio-T in the elder. Another conditions that may contribute to those hormonal alterations are metabolic syndrome, cirrhosis, HIV or use of 5 alpha reductase inhibitors, statins or betablockers (McBride et al., 2016; Ramasamy et al., 2015).

Genetic Implications

Unlike the ovarian function and its end with the menopause, spermatogenesis continues through life, which conditions differences in gametogenesis between the sexes. Each oocyte has 23 divisions with its 23 chromosome replications, and those do not go through any further DNA replication event. Before puberty, about 30 spermatogonial cell divisions occur in male. And after puberty, about 23 times per year, spermatogonial cells divide. This leads to spermatid chromosomes that have undergone as far as 610 replications by age 40 or 840 replications by age 50, with a remarkable increase in the number of de novo mutations with age (Kong et al., 2012). Lacking of a DNA repair system is common in elongated spermatids, immature and mature spermatozoa, worsening the situation.

Achondroplasia was the first genetic disorder related to paternal age, when observed by Weinberg as specially linked to last-born children of a sibship. Achondroplasia is the most common cause of dwarfism and affects, as an autosomal dominant disease, the fibroblast growth factor receptor 3 (FGFR3). FGFR2 is affected as well causing Apert syndrome, being one of the most studied disorders caused by paternal age, where the mutations 755C > G or 758C > G are found. Tiemann-Boege et al. marked interestingly that a 12-fold increased chance of fathering a child affected by achondroplasia was found in men of 50–54 years, while the relative risk of having sperm that carries the mutation was only doubled in them (Tiemann-Boege et al., 2002). Crouzon and Pfeiffer's syndromes are also related to FGFR2 and advanced paternal age. With that, the most common disorders affected by paternal age are autosomal dominant caused by mutations in FGFR2–3 genes, HRAS, PTPN11 and RET, conditioning disease like Apert, Crouzon, Pfeiffer and Muenke syndromes, achondroplasia, Costello and Noonan syndromes, multiple endocrine neoplasia type 2A and 2B (Conti and Eisenberg, 2016).

Aneuploidy is defined as a chromosomal numerical aberration and may occur as an error during meiosis of the gametes. Maternal errors are in origin of the vast number of human aneuploidy and, though every chromosome is candidate to nondisjunction, the 21 and sex chromosomes are described as the most commonly found. Trisomy 21 has been attributed to maternal aneuploidy in 93% of cases (Sartorelli et al., 2001). Regarding sex chromosomes, advanced paternal age has been related to an increase in XY sperm production. Lowe et al., when compared with the rate of XY sperm of 7.5/10000 in the 20 years group, determined an increase of 160% in men over 50 years. No evidence of age effect on frequencies of disomy X, Y or 21 were found (Lowe et al., 2001). An interesting point in relation to Klinefelter syndrome is the theory of the self-correcting aneuploidy, proposed to explain the fact of finding some foci of spermatogenesis in those patients. (Sciurano et al., 2009).

Malignancies

Parental age has been considered, as well, as a risk factor for malignancies. In fact, the increasing incidence of childhood cancer in the last decades has been attributed to improved detection methods and screening programmes, increased environmental risk factors and other epidemiological circumstances like paternal age. Yip et al. analyzed maternal and paternal age in a study in Sweden finding the most significant results in children under 5 years. Retinoblastoma was linked to maternal age. Leukemia was associated to both maternal and paternal age, but no association was found when maternal age was under 25 years, suggesting a main contribution of maternal factor. Central nervous system cancers risk was increased by paternal age, mainly to astrocytoma. Besides the association found, the proposed age ranges for the offspring may set a big contribution to generate and design screening campaigns focusing in the children group under 5 years (Yip et al., 2006).

Hematologic malignancies have been linked to paternal age. Lu et al. explained their finding of a 50% increased risk of non-Hodgkin lymphoma (NHL) in men over 40 years by several mechanisms. First of them, was the continuous replication of stem cells in male spermatogenesis comprising DNA damage. Aberrant epigenetic regulation may be altered by paternal age and might be another mechanism related to the increased incidence (Lu et al., 2010). In the literature, long leukocyte telomere length (LTL) in the offspring has been related, as well, as a predictor of increased NHL risk (Lan et al., 2009). Increased LTL may also have higher risk of breast cancer in daughters of old fathers (Arbeev et al., 2011). Telomeres are set at the end of the chromosomes and are repetitive sequences (TTAGGG) of non-coding DNA. Their function is to promote structural stability of the chromosomes and control cell division. They also have a role in cell durability, and in mice and human, long LTL showed evidence of increase longevity because its association with reduced risk of atherosclerosis. The aging and attrition of the telomere with successive cell division, avoids its natural protecting action for the chromosome, which becomes instable. Telomere shortening and malfunction produce cell apoptosis in the majority of cases. Not only leukocyte, muscle, skin and fat cells have been found to shorten their telomeres with increasing age. Telomerase is a protein with reverse transcriptase activity and adds TTAGGG sequences to the telomere when some repeats are lost by continuous cell division. This telomerase is highly found in germ cells and neoplastic cells. This controversy confronting longevity and cancer risks needs further studies to make this seemingly contradiction clear (Sharma et al., 2015).

Breast and prostate cancer are other malignancies proposed to have an association with maternal and paternal age. For female offspring, both maternal and paternal, have been related to breast cancer. But for male offspring, only paternal age have related to prostate cancer. Zhang et al. noted an overall increase of 70% in the risk of prostate cancer for sons sired by fathers over 38 years (Zhang et al., 1999).

Mental Health

An increasing number of papers have been recently published relating the paternal age to complex neuropsychiatric conditions like bipolar disorder, autism, schizophrenia, suicide attempt and, even, academic morbidity.

Autism spectrum disorders (ASD) are defined by impairment in social interaction, repetitive patterns of behavior and manifest difficulties to social communication or occupational development. ASD have been associated to paternal age and is usually recognized at early ages, usually in children under 3 years. Reichenberg et al. conducted their study in Israel and found that paternal age over 40 years, increased by 5.75 the autism risk in the offspring, when compared with fathers younger than 30 years. When considering age as a continuous variable, the odds of siring an autistic child doubled for each 10 years increase in paternal age (Reichenberg et al., 2006). In the same line, another important publication in Sweden, with more than 2,6 million individuals, reported an increased risk of having a diagnosis of ASD of 75% in the offspring of fathers over 45 years compared to father of 20 to 25 years. When accounting for all factors shared by siblings risk increased to 3.5 times when parental age was over 45 years (D'Onofrio et al. 2014).

The genetic implications for ASD include genetic, epigenetic and environmental factors but it is as strong as showed by the fact of finding a concordance rate of autism in monozygotic twins from 60% to 90% (Geschwind., 2009). But, not every author agrees with the theory of genetic mutation linked to paternal age to cause ASD. Those groups proposed other lines of causality like the potential difficulty for communicating with women or shyness and social impairment of those men, which may be related to any degree of ASD phenotypes found in these potential fathers (Puleo et al., 2008).

Finally in ASD, a transgenerational risk has been proposed as it has been reported a 1.79 increased risk of ASD for the offspring when maternal grandfather was over 50 years when he gave birth to his daughter. In the same line, risk goes to 1.67 for paternal grandfather. The high heritability of epigenetic factors has been pointed as an explanation (Frans et al., 2013).

Schizophrenia, being a disorder with an incidence of 10–22/100,000 persons per year, has been related as well to paternal age. Symptoms typically start at adolescence or early adulthood. Brown et al. in 2002 concluded that, when paternal age was considered as continuous variable, the analysis showed a strong trend to an association between paternal age and risk of adult schizophrenia spectrum disorders, proposing an adjusted rate ratio of 1.86 (adjusted to maternal age) for every 10 years increase in paternal age. If the focus was placed only in schizophrenia, the rate ratio was 1.89 (Brown et al., 2002). Another studied found an increased risk of psychosis (HR = 2.07) in advanced paternal age (D'Onofrio et al., 2014). The results of Sipos et al. with a cohort of 754.330 people born in Sweden found a hazard ratio for each 10 year increase in paternal age of 1.47 for schizophrenia and 1.12 for non-schizophrenic non-affective psychosis, confirming paternal age as a strong independent risk factor. A stronger association was found in subjects without a family history of schizophrenia, strongly supporting the theory of de novo mutations in the germ cells of older fathers (Sipos et al., 2004). Besides de novo mutations, parental constitutional factors like presence of schizophrenia spectrum disorders in either of the parents, have been proposed as an explanation. In the same line, environmental conditions like higher levels of psychosocial stress, physical illness in the father or becoming fatherless in the adolescence may have a role in the development of the disease (Brown et al., 2002).

Another psychiatric condition related to advanced paternal age is bipolar disorder, which is mainly diagnosed in the early adulthood. In the Sweden study by D'Onofrio et al. a HR of 7 was provided when adjusted for statistical covariates for men over 45 years (D'Onofrio et al., 2014). Another study analyzed 13,000 patients with bipolar disorder and found the offspring of men over 55 years were 1.37 times more likely to be diagnosed with bipolar disorder when compared with fathers under 25 years (Frans et al., 2013).

When considering cognitive capabilities, Aurox firstly associate the paternal age to impaired learning and conditioning in rats almost 35 years ago (Aurox., 1983). D'Onofrio et al. in their fixed-effects sibling models found an odds ratio of 1.59 for failing a grade and of 1.7 for low educational attainment for the offspring of fathers over 45 years when compared to those of 20–25 years (D'Onofrio et al., 2014). Another study showed paternal age was related to offspring intelligence, in this case nonverbal intelligence. The best scores were obtained by the group of fathers aged from 25 to 44 years, while fathers under 25 years or older than 44 years sired offspring with lower intelligence scores (Malaspina et al., 2005; Malaspina et al., 2015). Saha and colleagues published in 2009 two papers regarding how paternal age influenced neurocognitive outcomes and childhood behaviors. It was noticed that paternal age was associated with poorer scores in neurocognitive measures used (Bayles Scales, Stanford-Binet Intelligence Scale, Graham-Ernhart Block Sort Test, Weschler Intelligence Scale for Children and Wide Range Achievement Test). This results showed a linear progression when age of the fathers was grouped in 5 years intervals. Maternal age, conversely, was associated to higher scores in the same tests. The other publication by Saha et al. focused on childhood behaviors and concluded that advanced paternal age was associated with a significantly increased risk of adverse 'externalizing' behaviors (e.g. vandalism) at 7 years. For every 5 year increase in paternal age, the odds of higher 'externalizing' behaviors was increased by 12% even after adjusting for confounding factors. 'Internalizing' behavioral outcome was not associated with advanced paternal ages but was so with advanced maternal age (Saha et al., 2009a; Saha et al., 2009b).

Conclusions

Paternal age has been associated to many pathologies and conditions in the offspring, even in a transgenerational way. Nevertheless, there is no screening test aimed to detect those potentially deleterious factors in the aged father. Focused tests like sperm DNA damage may help to uncover a defect in spermatogenesis and be useful to select the most suitable method of ART. The clinical

practice guideline of the Society of Obstetricians and Gynecologists of Canada (SOGC) recommends in their last point of the list that “Advanced paternal age appears to be associated with an increased risk of spontaneous abortion and increased frequency of some autosomal dominant conditions, ASD and schizophrenia. Men over 40 years and their partners should be counseled about these potential risks when they are seeking pregnancy, although the risks remain small”. The American College of Obstetricians and Gynecologists (ACOG) also recommends counseling the partners with male age over 40 years. To date, despite the increased risk of disorders in the offspring, an old male’s partner pregnancy should be treated similar to any other pregnancy, according to the prenatal guidelines established by the American College of Medical Genetics (Kimberly et al., 2012; Toriello and Meck, 2008).

TREATMENT: MEDICAL

Overview Treatment and Male Reproductive Medicine

Alayman Hussein, Minia University, Minia, Egypt

© 2018 Elsevier Inc. All rights reserved.

Semen analysis is the initial test used for evaluation of infertility in men. Based on the results of semen analysis, causes of male infertility are categorized into azoospermia, oligospermia, asthenospermia and teratospermia. Erectile dysfunction and ejaculatory disorders contribute to causes of male infertility in an indirect way and are categorized as coital causes of male infertility. In management of male infertility in men, we try to reach a specific cause underlying semen abnormalities or ejaculatory disorders and target it with the suitable line of treatment. Unfortunately, many abnormalities in semen remain without a clear definite cause and are called idiopathic.

We have three options for treating male infertility. The first option is to specifically treat the cause either surgically as we do in varicocele and genital duct reconstruction or medically as in hormonal treatment of hypogonadotropic hypogonadism. The second option is an empiric medical treatment for idiopathic semen abnormalities. The third option is assisted reproduction techniques (ART). ART is reserved for cases beyond, or had failed trials of, surgical repair or medical treatment. The choice of treatment depends on many parameters which include the expected success rate of the selected treatment, the cost of treatment and the age and fertility status of the partner.

Unless we have a definitely surgically correctable cause, medical treatment of male infertility is the first option for most of the cases. Medical treatments are either specific or empiric. Generally, the trial of medical treatment is required to cover at least 6 months, equivalent to two cycles of spermatogenesis, before judging its efficacy and before deciding to shift into another line of treatment. In the process of deciding the suitable line of treatment of any case, it is necessary to perfectly study the medical history of the patients and know in details all drugs that have been used. It is known that chemotherapy, exogenous androgens, anabolic steroids, alpha blockers and SSRIs may affect the fertility potentials, and it is required to put in consideration stopping or modulation of the use of these drugs and to take the required precautions on its use.

Azoospermia

Azoospermia is a complete absence of sperm in semen even after centrifugation of the specimen and examination of the pellet. It may be obstructive azoospermia due to genital duct obstruction with normal spermatogenesis, or functional azoospermia due to failure of the testis to produce sperm in a sufficient number to be demonstrated in semen and is called nonobstructive azoospermia. Treatment of obstructive azoospermia requires genital duct reconstruction or sperm retrieval for intra cytoplasmic sperm injection (ICSI). There is no role for medical treatment in obstructive azoospermia.

Nonobstructive azoospermia is a complete absence of sperm in semen due to a defect in sperm production which is either due to abnormalities in the level of the hormones which are required for normal spermatogenesis, namely FSH and testosterone or due to intrinsic testicular defect (Jarow and Zirkin, 2005). The choice of medical treatment in patients with azoospermia requires an initial evaluation of the hormones related to spermatogenesis.

Specific Medical Treatment

Low FSH, LH and testosterone in patients with features of hypogonadism is the key for the diagnosis of hypogonadotropic hypogonadism. Despite the requirement for testosterone for normal spermatogenesis, the administration of exogenous testosterone and other androgens have a negative feedback on hypothalamic pituitary gonadal axis and inhibit the secretion of FSH and LH from the pituitary gland and consequently decrease intratesticular testosterone. So, exogenous androgens should be avoided. Hormonal replacement with hCG and hMG in these patients help to restore the normal level of FSH and LH and stimulate Leydig cells in the testis to produce testosterone and stimulate spermatogenesis (Kim et al., 2013). Nonobstructive azoospermic men start to demonstrate sperm in their semen after long term treatment with injection of hCG and hMG (Liu et al., 2002). An alternative method for restoring the normal level of FSH and testosterone and successfully produce sperm in men with hypogonadotropic hypogonadism is the use of pulsatile injection of GnRH (Pitteloud et al., 2002).

In cases with low testosterone in azoospermic men with normally developed sexual features, we need more hormonal evaluation to reach the specific cause of the decreased testosterone level. Assessment of serum level of FSH, LH, prolactin, estradiol and thyroid hormones are required to reach the etiology and select the type of hormonal treatment.

Empiric Medical Treatment

High levels of FSH and LH with low or normal testosterone in azoospermic men indicate a primary testicular failure and there is no role of medical treatment. The only option for these cases is micro TESE and ICSI.

But, in case of normal or slightly high level of FSH and testosterone, we can try empiric medical treatment. Clomiphene citrate was tried in men with idiopathic nonobstructive azoospermia and sperm were demonstrated in the ejaculate of some men after its administration (Hussein et al., 2005). The idea of starting an empiric treatment in patients with nonobstructive azoospermia is based on the fact that Clomiphene, which successfully improves sperm production in some cases of oligospermia, might be useful to produce enough sperm for ICSI either by resulting in sperm identified in the ejaculate or potentially improving outcomes of TESE. These results were encouraging and opened the door for further studies that established the value of medical treatment of such cases with a considerable degree of success.

When clomiphene is applied to all nonobstructive azoospermic patients prior to TESE without any histopathological studies, excluding patients with baseline FSH more than one and half the upper limit of normal, the response to clomiphene is not identical in all patients. Patients differ in the dose and regimen required to achieve the target level of testosterone and FSH. Some patients do not reach the target level of serum testosterone and FSH even if we use the maximum dose of clomiphene. Some patients respond to clomiphene treatment by an obvious increase in FSH without increase in testosterone. Few patients respond to clomiphene by an unexpected decrease in testosterone which is also manifested by decrease in sexual desire.

Based on these findings, and as it is believed that optimizing the level of hormones rather than the type of the used drug is the most important factor for the success of the medical treatment, the empiric use of different drugs in nonobstructive azoospermia and evaluation of their hormonal response and their outcome is evaluated. A protocol showing the value of optimizing the level of FSH and testosterone in men with nonobstructive azoospermia to adequately stimulate spermatogenesis demonstrated around 10% chance of producing sperm in semen after around 6 months treatment (Fig. 1). In addition, it is noticed that an obvious increase in the likelihood of finding sperm in micro TESE in patients in whom sperm didn't show up in their ejaculate. The drugs that are used in this protocol are the same drugs that are popularly used in the treatment of oligospermia and the hypothesis of the success of treatment in this protocol is to change the type and dose of the drugs to increase the level of FSH and total testosterone to a target level adequate for stimulation of spermatogenesis (Hussein et al., 2013).

Oligospermia

Oligospermia is a decrease in the sperm concentration in semen below 15 million sperm per milliliter (WHO, 2010). Oligospermia is a defect in sperm production and may be due to surgically correctable causes like varicocele, exposure to thermal or chemical environmental factors suppressing spermatogenesis, hormonal factors, intrinsic testicular defect or idiopathic.

Specific treatment of oligospermia requires proper evaluation of the patient to identify its cause. Oligospermia may be multifactorial and the patients are informed that smoking, exposure to heat or chemicals and wearing tight clothes may be additional causes of oligospermia. We advise the patients to modify their life style and avoid such factors that inversely affect the process of normal spermatogenesis. We try to identify surgically correctable causes and treat it properly. We look for hormonal abnormalities that might suppress spermatogenesis and start the specific hormonal treatment to restore the normal levels of FSH and testosterone.

In idiopathic oligospermia, we use the same protocol we described above for idiopathic azoospermia (Fig. 1). Drugs that are commonly used for the treatment of oligospermia include.

Gonadotropin: Exogenous gonadotropin treatments include the use of hCG and hMG.

hCG, which is analogous to LH, stimulates the Leydig cell secretion of testosterone.

hMG has both LH and FSH activity. The reason for gonadotropin administration in idiopathic oligozoospermia is based on its observed efficacy in the treatment of hypogonadotropic hypogonadism. However, their effectiveness for treating normogonadotropic oligospermia is less clear (Siddiq and Sigman, 2002).

Antiestrogens, Clomiphene and Tamoxifene: The antiestrogens indirectly stimulate the secretion of FSH and LH by blocking estrogen receptors in the hypothalamus, which increases the release of GnRH. Clomiphene citrate is prescribed in many different protocols.

Fig. 1 A protocol of empiric use of drugs for optimizing spermatogenesis regulating hormones in nonobstructive azoospermic.

The commonly used dose of Clomiphene is a 25-mg daily oral dose. Higher doses may cause down-regulation of the hypothalamo-pituitary gonadal system (Heller et al., 1969). Men treated with clomiphene citrate consistently demonstrate an elevation in serum FSH, LH and testosterone levels. As a result, serum gonadotropins and testosterone must be monitored periodically to ensure that the testosterone level remains within normal limits, because higher levels may negatively influence spermatogenesis. Small number of patients may suffer deterioration in semen quality with antiestrogen therapy. Therefore, frequent semen analysis is essential during follow-up (Gilbaugh and Lipshultz, 1994). Side effects of Clomiphene are rare and include nausea, headache, dizziness, weight gain, alterations in libido, visual field changes, gynecomastia and allergic dermatitis. These side effects are usually mild and occur in less than 5% of patients (Siddiq and Sigman 2002). Tamoxifen citrate has less estrogenic activity than clomiphene citrate. Tamoxifen is taken orally in doses ranging from 10 to 30 mg per day. Side effects are similar to those seen with clomiphene but occur with lower frequency because of its weaker estrogenic properties.

Aromatase inhibitors: Aromatase enzyme converts the circulating testosterone into estrogen within fat cells. Markedly obese men may have an excessive endogenous conversion of testosterone into estrogen. Alteration in the ratios of estrogen and testosterone may decrease pituitary levels of LH and FSH and impair sperm production (Kulin and Reiter 1972). Normal fertile men have a testosterone/estradiol ratio above 15 and men with a ratio less than 10 usually have a defect in sperm production. Aromatase inhibitors block the conversion of testosterone to estrogen, thereby increasing testosterone level enhancing spermatogenesis. Raman and Schlegel used anastrozole and testolactone in 140 patients with oligospermia and low testosterone and a low Testosterone/Estradiol ratio and found a significant increase in sperm count and motility in addition to the increases level of testosterone (Raman and Schlegel, 2002).

Teratospermia

Teratospermia means increase in the percentage of sperm with abnormal form in semen. Normally, normal sperm with strict criteria in semen should be at least 4% (WHO, 2010). Teratospermia reflects a defect in sperm maturation in the testis. Testosterone is responsible for the late stages of spermatogenesis and its low level in the testis might be a cause of teratospermia. So, hormonal manipulation to restore a normal level of testosterone is our medical choice for treatment of teratospermia. Teratospermia may also be due to causes beyond medical treatment like varicocele and cases of prolonged exposure to spermatotoxins.

Asthenospermia

Asthenospermia is a decrease in the percentage of sperm with forward progressive motility below the reference limit of 32% (WHO, 2010). Many cases of asthenospermia have unexplained etiology and may be due to intrinsic sperm abnormalities with a limited treatment outcome. Smoking and exposure to environmental spermatoxins thermal, chemical, or radiation may affect sperm motility. Parallel to any medical or surgical treatment of male infertility, patients are advised to give up smoking and adjust their lifestyle affecting scrotal heating such as prolonged time spent seated and avoid any habitual, occupational or environmental exposure to excessive heat, chemicals, and radiation.

One of the common treatable causes of asthenospermia is varicocele. There is no role for medical treatment for varicoceles because it is an anatomical abnormality that requires a microsurgical repair. Most of the studies demonstrate a significant improvement in sperm motility and other semen parameters after microsurgical varicocelectomy (Chiba and Fujisawa, 2016).

Causes of asthenospermia requiring specific medical treatment include infection, antisperm antibodies, hyperviscid semen and its delayed liquefaction. One or more of the following lines of treatment are used for the treatment of patients with asthenospermia:

Antibiotics

Infection of the male genital system, when suspected, should be evaluated and properly treated without any delay. Acute Testicular infection and testicular abscess may cause destruction of the functioning seminiferous tubules and complete damage of the testis. Gonorrhea and severe genital duct infection may be complicated with its obstruction and may cause obstructive azoospermia if occur bilaterally.

Chronic prostatitis and genital duct infection may change the pH of semen, produce of seminal reactive oxygen species and create unsuitable media for sperm vitality, motility, and DNA integrity (Athayde et al., 2007). All men with elevated seminal white blood cell should be evaluated for a genital tract infection or inflammation. When prostatitis and genital duct infection is suspected, semen culture should be performed. Unexpectedly, most of leukocytospermic samples are microbiologically negative. The most commonly found gram positive and gram negative bacteria are *Streptococcus fecalis* and *Escherichia coli*, respectively (March and Isidori, 2002). Also, Chlamydia trachomatis and Ureaplasma urealyticum are often involved and are expected in cases of negative gram stain culture.

Once genital duct infection is diagnosed, antibiotic therapy is initiated according to the results of semen culture. The commonly used antibiotics that are used for the treatment of chronic prostatitis and genital duct infections are Doxycycline, tetracycline, fluoroquinolones (levofloxacin, ciprofloxacin, ofloxacin, norfloxacin), cotrimoxazole (sulfamethoxazole 800 mg, trimethoprim 160 mg) and macrolides such as erythromycin. These drugs are administered for 2–4 weeks. The objectives of such treatment are

to reduce or eradicate microorganisms, normalize inflammatory changes in prostatic secretions and semen and improve sperm parameters (Weidner et al., 1999).

Antioxidants

A small amount of reactive oxygen species (ROS) is necessary for the normal function of sperm. But, it is found that the rate of infertility is increased in men with seminal fluid containing a high level of ROS (Sharma and Agarwal, 1996). Although, the exact mechanism by which ROS affect sperm integrity and motility is not clearly defined, it is found that reducing seminal ROS levels is necessary for natural pregnancy and assisted reproductive technologies. The human body employs a number of mechanisms to minimize the damage caused by the ROS by many mechanisms. The presence of antioxidants in seminal plasma is the most important mechanism against the damaging effect of ROS (Agarwal and Prabakaran, 2005). Accordingly, clinicians used to prescribe antioxidants to improve sperm count and motility.

The use of antioxidants in the treatment of male infertility is completely empirical and there is no specific recommendation on its use to improve sperm count or motility. The commonly used antioxidants include vitamins A, C and E, zinc, folate, selenium, and carnitine. The beneficial effect of these drugs in treatment of male infertility is not certain (Ko et al., 2014).

Corticosteroids

Oral corticosteroids are commonly used to suppress antisperm antibody production, but its value in the treatment to improve pregnancy rates in male infertility is doubtful. The significance of ASA in infertile men is controversial and there is no standardized protocol for its treatment. The presence of antibodies against spermatozoa in the serum and/or in the seminal plasma or on the sperm surface may have a harmful effect in fertilization. Antisperm antibodies (ASA) can lead to immobilization and agglutination of spermatozoa and interfere with sperm-egg interaction (Veron et al., 2016). Common causes of ASA include previous genital tract infection, testicular biopsy, testicular trauma, testicular torsion, and vasectomy (Arap et al., 2007).

Mucolytics

On ejaculation, semen is coagulated due to its protein content secreted by the seminal vesicle. Normally, approximately 20–30 min after ejaculation, liquefaction of semen occurs by the proteolytic enzymes secreted by the prostate and sperm gain motility after being freed from the seminal clot. Hyperviscosity and delayed liquefaction of semen is seen due to prostatic infection and hypofunction of the prostate (Motrich et al., 2005).

Hyperviscosity and delayed liquefaction of semen impair normal sperm movement in the female reproductive tract and decrease the chance of fertilization and spontaneous pregnancy (Mandal and Bhattacharyya, 1987). Patients with hyperviscosity and delayed liquefaction of semen are treated with mucolytic drugs that are used in the treatment of cough such as *N*-acetylcysteine, carbocysteine and bromohexine. In addition, to the standard treatment of chronic prostatitis is indicated if leucocytes are detected in semen.

Coital Infertility

In this category of male infertility, the testes and genital duct are anatomically normal and produce normal quantity and quality of sperm. But, the process by which semen is ejaculated into the partner's vagina is not integrated. The problem may be due to erectile dysfunction in which the patient is unable to start the intercourse or may be due ejaculatory disorders in the form of anejaculation, retrograde ejaculation or extravaginal insemination due to premature ejaculation.

Erectile Dysfunction

Normal erection is required for normal intercourse with intravaginal ejaculation. The etiology of erectile dysfunction may be due to psychological, hormonal, neurological or vascular factors and may be due to a mix of two or more factors. Viagra (Sildenafil) was introduced, in 1998, as the first successfully specific oral medication for erectile dysfunction. Other oral medications for erectile dysfunction include Sildenafil, Tadalafil, Vardenafil, and Avanafil. All drugs are more or less similarly effective in treating men with erectile dysfunction and their side effects are generally accepted.

The WHO recommends using oral medication as a first line treatment of erectile dysfunction and it is necessary to define a clear diagnosis of erectile dysfunction before starting treatment. These drugs could be used with a degree of success in all causes of erectile dysfunction. On sexual stimulation, these drugs enhance the release of nitric oxide and cause relaxation of the cavernous smooth muscles and increase arterial blood flow and filling the cavernous bodies with blood.

The use of oral medications to treat erectile dysfunction is a doctor's decision according to the medical condition of the patient. These medications are risky when used in hypotensive patients, in patients with heart failure and in patients using drugs containing

nitrate. The choice of the type of oral medication is a patient preference base on clear information from the treating doctor about the advantages and disadvantages of each drug.

The effective dose of the drug is variable according to the degree of erectile dysfunction. Usually we start with a small dose in young patient and in patients with recent and mild form of erectile dysfunction. We can adjust the dose of the drug, or shift into another drug, according to the response to its initial dose.

Testosterone is a medication that might be needed to treat erectile dysfunction in cases with low serum testosterone. But, in patients seeking fertility, exogenous testosterone is contraindicated because it inhibits the hypothalamo-pituitary-gonadal access and suppresses the production of FHS, LH, and testicular testosterone, and all are required for normal spermatogenesis. In these cases we can use drugs that stimulate testicular production of testosterone and increase intratesticular testosterone. Examples of these drugs are hCG which is given to stimulate Leydig cells to produce testosterone and antiestrogens, such as Clomiphene and Tamoxifen, which increase the production of LH and consequently increase testicular production of testosterone.

Anorgasmia

Anorgasmia is a condition in which the patient has a normal erection and practice intercourse normally, but is unable to reach the stage of orgasm and ejaculation in his sex cycle. Anejaculation is usually a psychological disorder and requires a psychiatric consultation and psychotherapy.

Anejaculation

Emission is the deposition of seminal fluid into the posterior urethra. Emission is under sympathetic control and requires the integrity of the vas deferens, seminal vesicles, prostate, and bladder neck. Ejaculation is the expulsion of the seminal fluid through the urethra and depends on the function of the perineal striated musculature. For clinical purposes, the term ejaculation is often used to include both events (Revenig et al., 2014).

Ejaculatory failure or anejaculation is actually a failure of seminal emission. The patient reaches orgasm and feels the contraction of striated perineal muscles but with complete absence of ejaculate. Anejaculation may be psychogenic or neurogenic. It is usually seen in patients with spinal cord injury and in patients with a history of retroperitoneal lymph node dissection. It is also common in patients using alpha blocker drugs (Table 1).

In treatment of anejaculation, it is necessary to stop or change any medication that affects the sympathetic function. Medical therapy is used to enhance seminal emission and partially or completely restore the antegrade ejaculation. In case of no response to such medications, the other lines of treatment of anejaculation are vibratory stimulation or electroejaculation to get their sperm for the assisted reproductive techniques such as IUI or ICSI (Barazani et al., 2012).

Drugs used in the treatment of anejaculation include Pseudoephedrine hydrochloride (60 mg four times daily) and Imipramine hydrochloride (25 mg QID). Pseudoephedrine hydrochloride is a sympathomimetic agent that stimulates the contraction of ejaculatory muscles and improves antegrade ejaculation. It seems to be more effective when used over a few days, usually 10–14 days, rather than as a single dose before intercourse. Imipramine hydrochloride has an anticholinergic property and has been reported to be successful in treatment of anejaculation. It blocks the re-uptake of norepinephrine at the nerve terminals, potentiating the adrenergic activity. Human chorionic gonadotropin: Injections of human chorionic gonadotropin have been reported to increase the incidence of nocturnal emissions. It is used in treatment of anejaculatory patients who has low to normal gonadal hormones (Jiann, 2016).

Table 1 Etiology of anejaculation

Traumatic	Spinal cord injury
Iatrogenic	Posterior urethra injury
	Retroperitoneal lymph node dissection
	Aortic aneurysmectomy
	Colorectal surgery
	Sympathectomy
Pharmacological	Alpha Blockers used in treatment of BPH
	Antihypertensives
	Antipsychotics
	Antidepressants
	Alcohol
Metabolic and systemic	Diabetes mellitus
	Multiple sclerosis
Others	Bone marrow transplant
	Psychological
	Idiopathic

Table 2 Etiology of retrograde ejaculation

Anatomic	Neurologic	Pharmacologic
Bladder neck surgery	Diabetes mellitus	Antihypertensives
Prostatectomies	Retroperitoneal lymphadenectomy	Antipsychotics
Urethral strictures	Colorectal surgery	Antidepressants
Meatal stenosis	Abdominal aneurysmectomy	
Bladder neck trauma	Aortoiliac bypass surgery	
Posterior urethral trauma	Spinal cord injury	
Extrophy and epispadias		
Posterior urethral valves		
Ectopic ejaculatory duct		

Retrograde Ejaculation

Normally at emission, both the bladder neck and the external urethral sphincter are closed when semen is deposited in the posterior urethra. Then, the external urethral sphincter open as the pressure builds up in the posterior urethra, while the bladder neck remains closed and contraction of the bulbospongiosus and ischiocavernosus muscles occurs resulting in the antegrade ejaculation (Gosling et al., 1981). Any process interfering with adequate closure of the bladder neck will result in retrograde ejaculation. Table 2 demonstrate different causes of retrograde ejaculation.

The principle of treatment of retrograde ejaculation is to close the posterior urethra to allow only antegrade passage of semen. The posterior urethral sphincter is under control of the sympathetic system (alpha-adrenergic). Medical treatment of retrograde ejaculation is applicable only in patients with an anatomically intact bladder neck. Patients with anatomical abnormalities of the bladder neck secondary to surgical or endoscopic intervention are certainly not responsive to medical treatment. Treatment of retrograde ejaculation is initiated with the same drugs (Pseudoephedrine and Imipramine) outlined for treatment of anejaculation (Shoshany et al., 2017). In case of no response to such medications, the other choice of treatment is sperm retrieval from the bladder for assisted reproduction techniques.

Premature Ejaculation

Premature ejaculation is a persistent occurrence of ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person and/or his partner wishes it. Premature ejaculation is considered an infertility problem if ejaculation occurs before vaginal penetration. Premature ejaculation is classified as primary (lifelong) characterized by onset from the first sexual experience or secondary (acquired) characterized by a gradual or sudden onset following normal ejaculation experiences before onset. Ejaculation is a sympathetic process and premature ejaculation is commonly seen in anxiety and stress. Erectile dysfunction may coexist in men with premature ejaculation and it is important to treat it first.

Various behavioral techniques have been beneficial in treating premature ejaculation in many cases and are advised for patients uncomfortable with pharmacological therapy. Behavioral techniques include the “stop-start” technique and the “squeeze” technique. The “stop-start” technique is a commonly advised program in which the partner stimulates the penis until the patient feels the urge to ejaculate. At this point, he and his partner stop and wait for the sensation to pass and then stimulation is resumed. In the “squeeze” technique, the partner applies manual pressure to the glans of the penis just before ejaculation until the patient loses his urge. Relaxation and distraction technique, at the time of feeling urge to ejaculate, is another behavioral technique may help men to delay ejaculation. Masturbation before anticipation of sexual intercourse is also a technique used by young men and helps to delay ejaculation at intercourse (Rowland and Cooper, 2011).

Pharmacological treatment of premature ejaculation is either topical or oral. On-demand topical anesthetic agents, applied shortly before intercourse, to the ventral surface of the glans have consistently shown efficacy in treating premature ejaculation (Atikeler et al., 2002). The antidepressants selective serotonin reuptake inhibitors are used to be used daily as oral medications for premature ejaculation. Dapoxetine is a short acting selective serotonin reuptake inhibitor and is specifically used on-demand for premature ejaculation (Russo et al., 2016).

Steroidogenic Dysfunction

The terms hypergonadotropic hypogonadism, primary hypogonadism, and primary hypoandrogenism refer to impaired testosterone synthesis caused by Leydig cell dysfunction (Sokol, 2009). It is well established that spermatogenesis is highly dependent on intratesticular testosterone synthesis (Jarow and Zirkin, 2005), although hypoandrogenism is poorly associated with sperm parameters (Patel et al., 2015). The prevalence of hypoandrogenism in men with oligozoospermia and with azoospermia due to spermatogenic dysfunction have been observed to be approximately 43% and 45%, respectively (Sussman et al., 2008). For those hypogonadal men who desire to protect their future fertility, exogenous testosterone should be discouraged as it has contraceptive effects, therefore it is astonishing that 25% of urologists are still prescribing exogenous testosterone to treat hypoandrogenism with male factor fertility (Ko et al., 2012). Except for gonadotropins, all of these methods described below to increase intratesticular testosterone synthesis, are considered off-label. In cases where the patient has azoospermia associated with low testosterone concentrations and significantly elevated LH levels, currently the only feasible treatment is surgical sperm extraction.

Clomiphene Citrate

Clomiphene citrate, originally approved for the treatment of ovulatory dysfunction in women, is a selective estrogen receptor modulator (SERM) that competitively binds to estrogen receptors and blocks the negative feedback at the level of hypothalamus and the pituitary. As a result, it indirectly enhances LH and FSH excretion from the anterior pituitary, stimulating Leydig cells in the testis to produce testosterone (Ross et al., 1980). Clomiphene citrate is a racemic mixture of two isoforms—enclomiphene and zuclophene.

Clomiphene citrate is well tolerated by most patients. Although uncommon, adverse effects include headache, dizziness, nausea, vomiting, gynecomastia, weight gain and hypertension (Kim et al., 2013). There is also about 1.5% of patients who presents with blurred vision, photophobia, and diplopia that are normally reversible with cessation of the medication. However, a small percentage of men may develop a paradoxical decrease in testosterone or a negative impact on sperm parameters (Ross et al., 1980), therefore it is imperative to check the bioavailable testosterone of every patients after 2 or 3 weeks of medication, in order to evaluate if titration of the dosage is needed or if clomiphene must be discontinued and replaced by another medication.

Ross et al. (1980) found that more than 50% of the patients responded within the first 3 months of treatment with the rest of the cohort responding after 6–15 months. Similarly, Guay et al. (2003) observed an increase in free testosterone in all men with hypogonadism and erectile dysfunction after 4 months of treatment. In a recent study by Mazzola et al. (2014) nearly 40% of hypoandrogenic men on clomiphene citrate were non-responders (response defined as 4200 ng dL^{-1} improvement in total testosterone levels after 6 months of treatment) being testicular volume and baseline LH level predictive of a positive response. Although sperm concentration is not the best marker for fertility, there has been reported a $7.7 \times 10^6 \text{ mL}^{-1}$ increase in sperm concentration between clomiphene citrate administration versus control (Bridges et al., 2015).

Clomiphene citrate has been also used in patients with azoospermia due to spermatogenic dysfunction, as the increase of intratesticular testosterone may lead to sufficient sperm in the ejaculate or may improve the overall success rate of testicular sperm extraction. In two different studies done by the same group, it was demonstrated that 64.3% of the azoospermic patients with hypospermatogenesis or maturation arrest showed sperm in their ejaculate after clomiphene citrate therapy (Hussein et al., 2005), and that 57.7% of patients prescribed clomiphene citrate had a successful microsurgical sperm retrieval as opposed to 33.6% of the control group (Hussein et al., 2012).

Recently, enclomiphene citrate, one of the single isomers of clomiphene citrate that has a pure estrogen antagonism, has demonstrated positive preliminary results, increasing morning testosterone levels, LH, FSH, DHT and estrogen, while preserving spermatogenesis (Wiehle et al., 2014).

Aromatase Inhibitors

Aromatase is a cytochrome P450 enzyme present in many body organs, like testes, prostate brain, bones and adipose tissue. Aromatase inhibitors have been widely prescribed for infertile male with relative excess estrogen to testosterone levels, measured as testosterone/estradiol (T/E) ratio (Schlegel, 2012). Aromatase inhibitors act on the 2A6 and 2C19 subunits of aromatase enzyme complex to block the conversion of testosterone and androstenedione into estradiol and estrone respectively (Chehab et al., 2015). This will indirectly increase GnRH pulses, subsequently positively affecting the pituitary by increasing FSH, which will act on the Sertoli cells to enhance spermatogenesis, and LH, which will act on the Leydig cell to secrete testosterone (Chehab et al., 2015).

Anastrozole is a non-steroidal, 3rd generation aromatase inhibitor which bind reversibly to the aromatase enzyme complex. Raman and Schlegel (2002) compared testolactone and anastrozole and showed that the group treated with anastrozole had

statistically significant increases in the T/E ratio and improved semen parameters. Side effects of anastrozole therapy are rare, and they include decrease in libido in less than 5% of the patients, and clinically insignificant transient liver function test abnormalities in about 7.4% of the patients. Recently, anastrozole was reported to improve endocrine parameters in 95.3% of men with hypoandrogenism with low T/E ratio and a subset of patients displayed significantly improved sperm parameters (Shoshany et al., 2017).

Letrozole is also a non-steroidal, 3rd generation aromatase inhibitor. When comparing anastrozole to letrozole, it was demonstrated an increase in sperm concentration, motility, and morphologically normal sperm in the ejaculate of patients treated with either letrozole or anastrozole. Although, the increase in sperm concentration was numerically greater for patients treated with anastrozole, it was not statistically significant (Gregoriou et al., 2012). Side effects were similar to anastrozole including decreased libido, headache, and transient liver enzyme abnormalities (Gregoriou et al., 2012).

Currently, there are no prospectively randomized controlled trials, and the use of aromatase inhibitors remains off-label. Further studies are needed to better evaluate the effects of these drugs on spermatogenesis and to evaluate pregnancy and delivery rates post-treatment.

Gonadotropins

Spermatogenesis depends on the stimulation of the testis by the anterior pituitary gland gonadotropins secretion. Exogenous gonadotropins administration is the only FDA approved medical therapy for idiopathic male, but they are not widely prescribed due to their high cost and invasive method of administration. Gonadotropins therapy can be in the form of direct pituitary stimulation (GnRH) or exogenous replacement of LH and/or FSH.

Human chorionic gonadotropin (hCG) is an LH analog. hCG include a molecular weight $\sim 36,000$ Da (Da), with two subunits: α -subunit with gene location: 6q12-q21 and 92 aminoacids; and β -subunit with gene location: 19q13.32 and 145 aminoacids (Cole, 2010). It has similar biological activity in stimulating Leydig cells to secrete testosterone and it indirectly improves spermatogenesis by increasing intratesticular testosterone levels. It can be used in incremental dosage until target testosterone level is achieved. If after 2 months the testosterone level is still not adequate or if after 18 months spermatogenesis did not improve, many authors consider adding human menopausal gonadotropin (hMG), which contains both FSH and LH, and its dosage administration is incremental until sperm concentration is adequate (European Metrodin HP Study Group, 1998a). Another form of replacement of pituitary LH and FSH is the usage of its recombinant molecules (rLH and rFSH).

The gonadotropic replacement regimen is dependent on the onset of the hypogonadotropic hypogonadism. If it happened before puberty, FSH and LH analog are both needed because FSH has not primed the Sertoli cells. If on the other hand it happens post-pubertal, only LH analog is needed (Howles et al., 2007). They are not widely prescribed because of their high cost and invasive method of administration. Clinically they are reserved for infertile male who failed conventional therapy with clomiphene citrate and/or anastrozole, or for patient who developed severe side effects on these latter medications. A consensus regarding optimal starting dosage is still lacking.

A Cochrane review of six randomized clinical trials with patients on gonadotropins (Attia et al., 2013), confirmed the overall positive effect on the infertile male with live birth rate of 27% versus 0% and spontaneous pregnancy rate per couple of 16% versus 7% in placebos. A pregnancy rate of 13.4% was achieved versus 4.4% for those without treatment (odd ratio, 3.03; 95% confidence interval, 1.30–7.09).

In an old study, authors used transmission electron microscopy to evaluate the ultrastructural analysis of spermatozoa prior to the start of rFSH therapy and 6 weeks post-therapy and found that rFSH treatment resulted in a higher number of morphologically normal spermatozoa. The electron microscopic findings indicate that treatment with rFSH may be an effective way to improve sperm quality in cases with oligoasthenoteratozoospermia (Strehler et al., 1997). It was demonstrated that 89.3% of the men with complete isolated hypogonadotropic hypogonadism treated with hCG followed by rFSH were able ejaculate some sperm and that 64.3% of them were ejaculating over $1.5 \text{ M sperm mL}^{-1}$, with improvements in motility and morphology (European Metrodin HP Study Group, 1998b).

Gonadotropins have been used in patients with azoospermia due to spermatogenic dysfunction. Theoretically it might improve the results of testicular sperm extraction and it may help induce the appearance of the sperm in the ejaculate. This effect is achieved by “resetting” of the FSH and LH receptors in the Leydig and Sertoli through the high levels of exogenous gonadotropins, while there is a defective or inefficient quantities of bioactive FSH and LH (Wang et al., 1987). Multiple small studies have demonstrated clinically that treatment of NOA patients with recombinant FSH increased the chance of sperm retrieval on a second TESE, after a failed first attempt. Shiraishi et al. found a 22% success rate of retrieving sperm with 5000 IU treatment after a failed initial TESE (Shiraishi et al., 2011). Selman et al. performed a similar experiment with incremental dosage regime of rFSH and found similar positive rate of 22% (Selman et al., 2006). Ramasamy et al. demonstrated the same positive outcome in the Klinefelter group of patients (Ramasamy et al., 2009).

Pituitary Dysfunction

Hypogonadotropic hypogonadism occurs when the pituitary hormones LH and/or FSH are suppressed. One of the possible causes for hypogonadotropic hypogonadism is Kallmann syndrome, which consists in anosmia associated with decreased pituitary

function with autosomal dominant inheritance (although X-linked and autosomal recessive patterns were also observed) (Sokol, 2009). Treatment includes replacement of the pituitary hormones by exogenous gonadotropins that exhibit LH and/or FSH-like activities. In a recent publication in Japan, researchers looked at 55 adolescents with male hypogonadotropic hypogonadism. In regard to spermatogenesis, 76% of the patients treated with hCG-rFSH combined therapy showed positive results, though ranging in levels; impaired spermatogenesis was observed in some men with congenital hypogonadotropic hypogonadism while all men with acquired hypogonadotropic hypogonadism had favorable spermatogenesis (Sato et al., 2015).

Pituitary tumors and diseases that infiltrate its parenchyma, such as sarcoidosis, histiocytosis, hemochromatosis, and infections, may result in varying degrees of LH and FSH suppression. The most common kind of pituitary tumor that is related to male infertility secretes prolactin. In general, mild elevations of prolactin (below $50 \mu\text{g L}^{-1}$) do not warrant further evaluation (Niederberger, 2011). In cases where surgery is not indicated, dopamine agonists such as bromocriptine and cabergoline may be prescribed, with the last one showing fewer side effects (Klibanski, 2010).

Iatrogenic Dysfunction

The most common cause of testicular hypofunction is testosterone replacement therapy. The administration of exogenous testosterone leads to direct inhibition of the HPG axis as well as indirect inhibition through increased peripheral aromatization. Some substances also show steroid-like effects such as spironolactones, opioids, and phytoestrogens (Hotelling and Patel, 2014). Furthermore, as many as 20% of legally sold sports nutrition supplements contain synthetic anabolic-androgenic steroids (Ohlander et al., 2016). Anderson and Wu reported that 70% of men developed azoospermia or severe oligozoospermia after 18 months of exogenous testosterone therapy with only 85% experiencing recovery of spermatogenesis (Anderson and Wu, 1996). In men with azoospermia or severe oligozoospermia due to exogenous testosterone therapy, Wenker et al. observed that introduction of HCG in combination with clomiphene citrate, tamoxifen, anastrozole or recombinant FSH was responsible to demonstrate a return or improvement of spermatogenesis in 47 of the 49 subjects (Wenker et al., 2015).

Obesity also contributes to hormonal dysfunction, since estrogen excess from peripheral aromatization in adipose tissue can inhibit the pituitary function and spermatogenesis. It is also reported that abnormalities in the metabolism of IGF-1, glucocorticoid excess, and increased testicular temperature are factors that could cause pituitary and testicular dysfunction leading to hypospermatogenesis (Hotelling and Patel, 2014). Therefore, although there is no clinical evidence to date, weight loss theoretically could improve overall semen parameters.

Endocrine Stimulatory Therapy for Testis Sperm Extraction

Moshe Shapiro and Samuel Ohlander, University of Illinois-Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Infertility, defined as the inability to conceive after 12 months of unprotected intercourse, affects roughly 15% of couples attempting to conceive (Cocuzza et al., 2013). Approximately 10%–15% of infertile males, and 1% of the general population, are azoospermic. Azoospermia is the absolute absence of sperm in the ejaculate. Prior to the development of intracytoplasmic sperm injection (ICSI) in 1989 and the utilization of testicular sperm extraction in 1995, men with azoospermia due to spermatogenic dysfunction (ASD), also commonly known as nonobstructive azoospermia, were unable to father their genetically own children. The only options for children were donor sperm or adoption. With the advent of ICSI, and the subsequent coupling with surgical sperm retrieval, single sperm harvested from the testicle were able to be manipulated and used for fertilization. Sperm develops in the seminiferous tubules, advances through the rete testis and then the epididymis, where it becomes capacitated and able to penetrate and fertilize an ovum (Bedford et al., 1973). ICSI directly injects the sperm into the ovum mechanically. This enables testicular sperm to be used for IVF to achieve pregnancies with similar success as compared to ejaculated sperm (Hussein et al., 2012). Further modification of the surgical retrieval utilizes a high power surgical microscope to intraoperatively identify dilated seminiferous tubules, or microsurgical testicular sperm extraction (microTESE), that have higher odds of obtaining sperm (Schlegel, 1999). It has been posited that endocrine manipulation of the hypothalamic-pituitary–testicular axis prior to surgical harvest can improve sperm retrieval rates and, in some patients, even induce sperm to appear in the ejaculate (Hussein et al., 2005). This article will discuss the means of endocrine stimulatory therapy prior to sperm retrieval.

Spermatogenesis

Spermatogenesis is the production of sperm. It occurs within the seminiferous tubules that comprise much of the testicular volume (Turek, 2016). The seminiferous tubules consist of germ cells, which are the progenitor cells for sperm, and support cells. These support cells include Sertoli cells, fibrocytes, and myoblasts. The complete cycle of spermatogenesis takes approximately 64 days (Clermont, 1972). Spermatogenesis occurs in a continuous and asynchronous manner, meaning, that at any one time, there are multiple different gametes at varying levels of maturity. For adequate spermatogenesis to occur, high levels of intratesticular testosterone are needed—typically at least greater than 10 times serum concentration and can approach greater than a hundredfold increase (Jarow and Zirkin, 2005). This high testosterone gradient compared to serum is maintained by local (testicular) production of testosterone by Leydig cells with the intratesticular testosterone kept locally high via the countercurrent gradient between the pampiniform venous plexus, with high testosterone levels diffusing to the testicular artery with lower testosterone levels (Jarow and Zirkin, 2005). When intratesticular testosterone levels decrease, spermatogenesis can be suppressed and may even cease altogether. Intratesticular testosterone levels are controlled by the multi-organ negative feedback regulatory system known as the hypothalamic-pituitary–testicular axis (HPTA) (Caroppo, 2009).

Hypothalamic-Pituitary–Testicular Axis

Male androgen levels and spermatogenesis are maintained by the HPTA (see Fig. 1). The HPTA is a finely tuned system controlled with multiple levels of stimulation and inhibition. Dedicated hypothalamic neurons secrete the peptide hormone gonadotropin releasing hormone (GnRH) in a pulsatile manner (Caroppo, 2009). The GnRH is transported through the portal system between the hypothalamus and the anterior pituitary. In the pituitary gland, extracellular receptors on gonadotrope secreting cells bind GnRH and, depending on the nature of the frequency of GnRH secretion, they secrete the gonadotropins follicle stimulation hormone (FSH) and luteinizing hormone (LH) (Caroppo, 2009). LH and FSH act in the testis to promote steroidogenesis and spermatogenesis, respectively. Testicular peptides and steroids then act upon the pituitary and hypothalamus with negative feedback. LH acts upon testicular Leydig cells to stimulate testosterone production, and FSH binds to Sertoli cells thereby promoting spermatogenesis. For normal spermatogenesis to occur, the HPTA must remain intact to maintain the appropriate intratesticular environment.

Azoospermia

Azoospermia is defined as the absence of any sperm in the semen, as opposed to aspermia, which is a lack of fluid where no anterograde specimen is produced at all. Azoospermia is diagnosed by centrifugation and microscopic evaluation of the pellet on two separate semen specimens to differentiate between cryptozoospermia, where small amounts of sperm are present (Corea et al., 2005). Azoospermia is typically categorized as either obstructive azoospermia, or, azoospermia due to spermatogenic dysfunction (ASD). Differentiation may often be delineated via thorough medical and surgical history (e.g., past vasectomy), though in less clear instances, laboratory evaluation may offer significant insight. In a patient with a FSH level of 7.6 mIU/mL

Fig. 1 Hypothalamic-pituitary-testicle axis.

- Anastrozole inhibits Aromatase blocking the conversion of testosterone to estradiol.
- Clomiphene citrate selectively blocks estrogen receptors, thereby blocking hypothalamic and pituitary negative feedback by estradiol.
- HCG, an LH analog, stimulates Leydig cells and testosterone production.
- hMG, includes both LH and FSH, and stimulate both Sertoli and Leydig cells.

or less, as well as testicular long axis of >4.6 cm, there is a 96% chance of azoospermia due to obstruction (Schoor et al., 2002). In patients with FSH levels >7.6 and testicular long axis length of <4.6 cm, there is an 89% chance of azoospermia due to spermatogenic dysfunction (Schoor et al., 2002). Given this data, diagnostic testicular biopsy is no longer routinely used and, if exam and serum assays indicate spermatogenic dysfunction, the physician may proceed confidently with discussions on surgical sperm retrieval and coupled assisted reproduction.

Microsurgical Testicular Sperm Extraction

For ASD, microTESE offers the greatest likelihood of successful sperm retrieval with retrieval rates of approximately 40%–60% (Esteves et al., 2011). The testicular parenchyma is divided into multiple compartments by septa into lobes, and within the lobes seminiferous tubules surround a central artery and the developing germ cells reside in each seminiferous tubule (Setchell and Brooks, 1988). The premise behind microTESE is that, even in an azoospermic man, there may be some pockets of spermatogenesis present within the testicle in some singular seminiferous tubules. Using high powered surgical magnification, these pockets of tubules are identified with the functional and sperm laden tubules appearing more gravid and fuller, as compared to the rest of the spermatogenic tubules.

MicroTESE became the gold standard for obtaining sperm in men with ASD when Schlegel showed sperm retrieval superiority with less testicular damage as compared to TESE without surgical microscope assistance (Schlegel, 1999). Despite this improved retrieval technique, 40%–60% of men with ASD will still be unable to father a biological child, thus there is impetus to improve the rate of retrieval and ability to predict success.

Medical Management for Azoospermia

Medical management of azoospermia is predicated on the theory that, increasing intratesticular testosterone will lead to clinically increased spermatogenesis (Jarow and Zirkin, 2005). In their seminal work, Hussein et al. showed that administration of clomiphene citrate, a selective estrogen receptor modulator, to men with spermatogenic dysfunction led to both the appearance of sperm in the ejaculate in some men, as well as improved sperm retrieval rates in patients undergoing microTESE (Hussein et al., 2012). Medical management acts by either direct stimulation of the testicles, or by inhibiting negative feedback leading to increased endogenous LH secretion with subsequent rise in serum and testicular testosterone (Boyle, 2009).

Indications for Endocrine Stimulatory Therapy

As most cases of male infertility are idiopathic in nature, management is typically empirical. In patients with a clear deficiency of the HPTA, such as in hypogonadotropic hypogonadism or exogenous testosterone use, medical management is clearly indicated. In

patients with an obstructive etiology, there is no deficiency in spermatogenesis, and, thus, stimulation is not indicated, and patients can be counseled to proceed directly to surgical extraction or reconstruction. In a patient with no fertility potential at all, such as with chromosome Y AZFa microdeletion, both endocrine stimulatory therapy and microTESE itself are contraindicated and futile (Oates and Lamb, 2009). However, since most patients presenting with ASD will have no identifiable cause, empiric therapy can and should be considered for those who are found to be hypogonadal. Unfortunately, there is no clear consensus on the appropriate testosterone cut point for the initiation of therapy. There is also variability in the use of total testosterone, free testosterone, and bioavailable testosterone for laboratory evaluation. Our recommendation is the use of bioavailable testosterone, calculated from any of the widely available online calculators that utilize serum testosterone, albumin, and sex hormone binding globulin (SHBG). In a study evaluating the use of bioavailable testosterone and sex hormone binding globulin, patients with both low overall testosterone and low bioavailable testosterone had worse sperm parameters (Ring et al., 2017). This difference was seen at the cutoff of a bioavailable testosterone of 156 ng/dL, despite patients with azoospermia being excluded from the study, this cutoff could be used to identify patients in whom endocrine stimulation prior to microTESE may be beneficial. Given that spermatogenesis takes approximately 2 months and endocrine stimulation can take up to 7 months for a response, great weight must be placed on factors other than the patient himself such as maternal age, timing of the female partner's cycle, as well as the availability of the IVF team, patient, and spouse.

Methods of Endocrine Stimulatory Therapy

Testicular endocrine stimulation is done either directly, to increase intratesticular testosterone and stimulate spermatogenesis, or indirectly, through suppression of negative feedback (Boyle, 2009). Optimally, in patients presenting with azoospermia due to spermatogenic dysfunction, an etiology of the azoospermia must be ruled out. In patients with a known etiology of their spermatogenic dysfunction, the goal of therapy is to restore the HPTA. When hypothalamic defects such as Kallman syndrome or idiopathic hypogonadotropic hypogonadism are present, stimulation of either the pituitary via gonadotropin releasing hormone (GnRH) or the testes themselves via FSH and human chorionic gonadotropin (HCG), a hormone endogenously produced by the placenta with an identical subunit and, thus, nearly biologically equivalent activity to LH, can be therapeutic targets (Dabaja and Schlegel, 2014). Another known cause of azoospermia due to spermatogenic dysfunction is exogenous testosterone administration. Exogenous testosterone administration leads to negative feedback at the level of the hypothalamus and pituitary decreasing LH and FSH secretion. This suppresses endogenous testicular production of testosterone and a decrease in intratesticular testosterone levels, impairing normal spermatogenesis. In a case series, these patients who had long-term exposure to exogenous testosterone were given HCG based regimens in addition to either a selective estrogen receptor modulator, an aromatase inhibitor or FSH. All the men tolerated the HCG regimen well, and 95.9% of men had return of spermatogenesis, with good sperm levels in the ejaculate (Wenker et al., 2015). In most men however, the etiology of their azoospermia is unknown, and treatment is empirical in nature, and seeks to stimulate the HPTA in the absence of a clear defect.

Currently, the only FDA approved drugs to treat male infertility are gonadotropins, including various formulations of LH and FSH (Chehab et al., 2015). GnRH is used in a pulsatile manner to induce endogenous pituitary secretion of the gonadotropins LH and FSH, though it is not available in the United States outside of specialty centers and clinical trials (Chehab et al., 2015). Men with Kallman syndrome or hypogonadotropic hypogonadism respond well to pulsatile GnRH therapy; however, there is little evidence to support its use in men with idiopathic spermatogenic dysfunction. Response to treatment can occur after 3 months of therapy. GnRH's utility is also limited by its scarce commercial availability, usually restricted to clinical trials and specialty centers, as well as a need for either a subcutaneous medication pump or frequent injections (Dabaja and Schlegel, 2014).

LH and its biological activity equivalent, human chorionic gonadotropin (HCG), are available in the US. Recombinant LH has a short half-life and has limited clinical utility compared to HCG, which has a much longer half-life and is more commonly used (Chehab et al., 2015). FSH is available in several formulations, as well as a purified urine product consisting of both LH and FSH, called human menopausal gonadotropin (hMG). In men with azoospermia due to spermatogenic dysfunction, HCG has been shown to reduce intratesticular fibrosis and increase Leydig cell size, compared to men with obstructive azoospermia (Oka et al., 2017). In men with hypopituitarism, gonadotropins are used. Initially starting therapy with HCG. If adequate androgenization occurs and the patient remains azoospermic, then FSH treatment can be introduced (Dabaja and Schlegel, 2014). Typically, a response can take up to 7 months to obtain sperm in the ejaculate and pregnancy occurs after an average of 28 months (Dabaja and Schlegel, 2014). In men with idiopathic spermatogenic dysfunction, there is lack of consensus regarding treatment with gonadotropins.

Selective estrogen receptor modulators (SERM), including clomiphene citrate (CC) and tamoxifen, act centrally at the hypothalamus and pituitary, where they disrupt the usual negative feedback of estrogen (Boyle, 2009). This leads to increased gonadotropins—mainly LH, with some FSH elevation as well (Hussein et al., 2012). SERMs are used to treat breast cancer and osteoporosis in women; however, their use in men to treat hypogonadism and infertility is off label. There is no clear consensus to the utility of SERMs in idiopathic infertility, with different meta-analysis having mixed results as to the efficacy of SERMs (Cocuzza et al., 2013; Willets et al., 2013). Regardless of findings regarding efficacy, CC and tamoxifen were well tolerated. Occasionally there can be a paradoxical effect from CC, with decreased testosterone levels after administration (Hussein et al., 2012). This may be due to clomiphene consisting of two isomers (*cis*) zuclomiphene and (*trans*) enclomiphene (Hill et al., 2009; Rodriguez et al., 2016). Zuclomiphene has been found to be an estrogen receptor agonist and enclomiphene is thought to competitively inhibit estrogen centrally (Rodriguez et al., 2016). It is also thought that the zuclomiphene component of CC may be responsible

for the estrogenic side effects of CC in men including the rare paradoxical response to CC. Enclomiphene citrate, under the trade name Androxal, is currently under development (Rodriguez et al., 2016). Additionally, there is a risk of pituitary enlargement and visual field disturbances (Chehab et al., 2015).

Estrogen in the male is a product of aromatized testosterone. Aromatase is present in adipose tissue as well as in the Leydig cells of the testes. Estrogen is the primary negative feedback molecule in the HPTA (Caroppo, 2009). High estrogen levels with low testosterone levels have also been shown to inhibit spermatogenesis. Aromatase inhibitors act by blocking peripheral conversion of testosterone into estrogen in adipose tissue and in the testes (Boyle, 2009; Schlegel, 2012). This leads to a cessation of negative HPTA feedback which induces increased secretion of gonadotropins. In a noncontrolled study, aromatase inhibitors such as anastrozole or letrozole improved patients' biochemical profile, semen parameters, and fertility (Schlegel, 2012). Patients who had the best response to aromatase inhibitors were men with a ASD or oligoasthenospermia, low testosterone and a low testosterone to estrogen ratio (Schlegel, 2012). Aromatase inhibitors are usually well tolerated; side effects include decreased libido, mildly elevated liver function tests, and nausea. Importantly decreased bone mineral density can occur due to lack of estrogen, hence long-term use of aromatase inhibitors in males is not recommended.

In a randomized controlled double blinded study comparing CC to anastrozole, CC was shown to raise serum testosterone levels significantly more than anastrozole; however, no difference in semen parameters or patient reported outcomes were seen (Helo et al., 2015). As CC selectively acts solely at the pituitary, bone density is maintained, and can be continued if the patient had been symptomatic from hypogonadism.

Procedural Outline

When testis endocrine stimulation prior to microTESE is indicated, a stepwise treatment can be implemented (see Fig. 2). However, as time may be of the essence due to advancing maternal age, frequently only one or two regimens are used prior to microTESE (Hussein et al., 2005). A common approach starts with an inexpensive, safe, oral medication, such as CC or anastrozole depending upon hormone profile, followed by symptomatic and laboratory evaluation of response after 2–4 weeks of therapy. If there is inadequate response, either due to side effects, lack of appropriate increase in serum testosterone, or disproportionate increase in serum estradiol, one can either increase the dose, switch medications, or add medications depending on the nature of the response. For example, a patient started on CC with good response of testosterone and normal estradiol can maintain the CC for at least 2–3 months before proceeding to microTESE (Hussein et al., 2005). If that patient were to have elevated estradiol, visual field disturbances, or an unchanged serum testosterone, they could switch to anastrozole, again measuring response. If the testosterone were unchanged, but FSH were elevated, then HCG could be added to spur testosterone production and so on, with the principle of safely raising testosterone and FSH. Fig. 2 provides an algorithm for implementation of therapy, though it ought to be noted that the algorithm is merely a guide, and patient specific management must be modified based upon tolerance, laboratory response, and reproductive timeline.

Fig. 2 Algorithm for endocrine stimulation prior to microTESE.

Outcomes

Several studies have debated the utility of endocrine stimulation of the testis to optimize sperm retrieval rates from microTESE (Boyle, 2009; Reifsnnyder et al., 2012; Hussein et al., 2012). An elegantly designed multi-center, prospective, randomized controlled trial demonstrated significant benefit, with improved rates of sperm retrieval after endocrine stimulation compared to non-stimulated controls with azoospermia due to spermatogenic dysfunction (Hussein et al., 2012). In this study, 612 patients were randomized to either a control, in which a microTESE was performed without any endocrine manipulation, or to an intervention cohort. Intervention included clomiphene citrate administration, with measured response guiding further interventions. Interventions included dose escalation of CC, addition of HCG, cessation of CC, and initiation of hMG in conjunction with HCG. All interventions were directed to a goal of a 50% increase of baseline FSH and serum testosterone levels of 600–800 ng/dL. In the intervention cohort, 10% of patients developed sperm in their ejaculate, with significantly improved sperm retrieval rates of 57% compared to 34% in the control patients (depending on regimen $P < 0.001$ – 0.05) (Hussein et al., 2012). Conversely, in the largest study supporting no benefit, the target testosterone was significantly lower, aiming for testosterone levels > 300 ng/dL (Reifsnnyder et al., 2012). Endocrine stimulation is well tolerated in general. Hence, the decision to proceed with endocrine stimulation prior to microTESE should include consideration of risks, benefits, costs, timing, and maternal age. However, in patients with diagnoses that are associated with irreversible infertility, such as certain chromosomal microdeletions, such therapy, as well as pursuing microTESE itself, would be inappropriate (Boyle, 2009).

Summary

Azoospermia due to spermatogenic dysfunction is a common cause of male factor infertility in patients presenting for an infertility evaluation. Studies have shown that with endocrine stimulatory therapy, there is an increased chance for successful sperm retrieval surgery. Endocrine stimulatory acts by raising intratesticular levels of testosterone produced by Leydig cells, improving the testicular histological environment and stimulating supportive Sertoli cells with FSH. Clomiphene citrate is frequently a first line, albeit off label, drug used to prompt testicular response, as well as HCG, anastrozole, and hMG. Sperm retrieval rates are improved in patients undergoing endocrine stimulatory therapy as compared to patients electing to proceed directly to surgical extraction, and some patients may even get sperm in the ejaculate. It is important to remember, however, that endocrine stimulatory therapy can take some time until titrated adequately, and, therefore, the treatment plan must take into consideration all factors including partners age and fecundity.

Ejaculation Disorders

Ejaculation Physiology, Anatomy and Dysfunction

Ejaculation is a complex process comprised of two phases: emission followed by expulsion. Following emission, during which time semen collects in the prostatic urethra, the bulbar urethra rapidly distends. Distension of the bulbar urethra triggers the expulsive phase of ejaculation, at which time the semen is rapidly propelled along the penile urethra by contraction of the bulbocavernosus muscle (Puppo & Puppo, 2016). Closure of the internal urethral sphincter is crucial to antegrade ejaculation, preventing retrograde flow of semen into the bladder.

The complex process of emission and expulsion is coordinated by sympathetic efferent fibers (T10-L3) (Jefferys et al., 2012). Spinal cord injuries, as well as peripheral neuropathies, including iatrogenic injury during retroperitoneal and pelvic surgery, can result in partial or complete bladder neck dysfunction (Goldwasser et al., 1983). Once bladder neck dysfunction occurs and retrograde ejaculation (RE) is noted, medical treatment can be offered to return antegrade flow during expulsion. Other patients may suffer from delayed or complete absence of ejaculation, while the last group of patients may have premature ejaculation (PE).

Medical Therapy of Retrograde Ejaculation

Medical treatment for RE is based on increasing bladder neck contractility, either through increasing sympathetic tone or decreasing parasympathetic activity. Tricyclic antidepressants, such as imipramine, along with alpha agonists, such as pseudoephedrine, have been found to increase the pressure profile in the posterior urethra (Goldwasser et al., 1983), successfully increasing antegrade ejaculation. Imipramine and pseudoephedrine are two medications commonly utilized for treatment of RE.

Pseudoephedrine is an α -adrenergic agonist that is readily absorbed from the gastrointestinal tract with a short onset of action and has a half-life of about 5–8 h (Kanfer et al., 1993). The maximum recommended dose is 240 mg each day. Sympathomimetic adverse events include various degrees of dizziness, sleep disturbances, weakness, restlessness, dry mouth, nausea, and sweating, and these can occur frequently in patients who respond to therapy (Kamischke & Nieschlag, 1999).

Imipramine is a tricyclic antidepressant whose response is mediated through both anticholinergic and slight alpha agonist effects. Dosing is typically 25–50 mg for 7 days prior to planned ejaculation or ovulation of partner. Side effects include dizziness, weakness, nausea or excessive sweating (Ochsenkühn et al., 1999).

The overall efficacy of these medications is variable, and studies evaluating their effect are limited to small non-randomized case studies. Overall, the efficacy for return of antegrade ejaculation is around 30% for pseudoephedrine and 35% for imipramine (see table for literature on success rates).

Paper	Drug	Sample size	AE achieved	% AE Achieved

Many prefer treatment of retrograde ejaculation with oral pharmaceuticals described above, as it allows the ability for spontaneous pregnancy. However, when antegrade ejaculation cannot be pharmacologically induced, bladder alkalization and sperm retrieval from postejaculatory urine is also an option.

Successful recovery of spermatozoa from postejaculatory urine requires careful regulation of both pH and osmolality of urine, and subsequent separation of motile sperm from bladder debris and other cells (Braude et al., 1987). Prior to ejaculation, the urine must be alkalized, which can be accomplished with either oral sodium bicarbonate or intravesicle instillation of Ringer's lactate

(LR) solution (Hotchkiss et al., 1954). To obtain retrograde ejaculated sperm without bladder catheterization, patients are instructed to drink solution containing 3 g/L sodium bicarbonate prior to ejaculation. Prior to ejaculation, patients must empty bladder and verify urinary pH has been neutralized. Following ejaculation, urine must be voided and collected within the hour (Jimenez et al., 1997). For urinary sperm retrieval using bladder irrigation, the bladder is first emptied and washed with LR solution via catheterization, and then a small volume (~30 mL) of the solution is instilled into the bladder. The catheter is removed, prior to ejaculation, and spermatozoa are obtained either by voiding or catheterization (Philippon et al., 2015).

Once the postejaculatory urine sample is obtained, it is centrifuged, and re-suspended in sperm washing buffer for use in IUI or ICSI only (sperm retrieved with this technique cannot be used to achieve spontaneous pregnancy). There are no studies examining the effectiveness of this approach to managing retrograde ejaculation (Mehta & Sigman, 2015), although pregnancy rates with the use of retrieved sperm for UI vary from 20% to 50% (Braude et al., 1987; Silva et al., 2000; Nikolettos et al., 1999; van der Linden et al., 1992; Shangold et al., 1990).

Medical Therapy of Delayed Ejaculation

Drug treatment of DE ejaculation has met with limited success. Many medications have been proposed as treatment strategies for delayed ejaculation, including cabergoline, amantadine, and even testosterone (Abdel-Hamid et al., 2016). These drugs can facilitate ejaculation by either a central dopaminergic (cabergoline), anti-serotonergic (bupropion), or oxytocinergic (oxytocin) mechanism of action or a peripheral adrenergic mechanism of action (midodrine) (Abdel-Hamid et al., 2016; Hsieh et al., 2012; Modell et al., 1997; Ishak et al., 2008). However, the evidence supporting pharmacological treatment of delayed ejaculation is relatively weak and limited to case reports, small case series and small trials (Abdel-Hamid et al., 2016). Currently, no drugs have been approved by regulatory agencies for this purpose and most drugs that have been identified for potential use have limited efficacy, impart significant side effects, or are as yet considered experimental in nature (McMahon, 2016).

Medical Therapy of Premature Ejaculation

Premature ejaculation (PE), is one of the most common male sexual disorders: According to the National Health and Social Life Survey, PE was reported to have a prevalence of 21% in men aged 18 to 59 in the United States (Laumann et al., 1999). In addition to sexual dissatisfaction, severe premature ejaculation that prevents successful coitus will likely impact a couple's ability to conceive naturally.

The exact etiology of PE is unknown and treatment is based on psychological, behavioral and pharmacological interventions. Behavioral and psychological therapy are often the first lines of treatment for patients presenting with PE. Psychotherapy includes both sexual therapy and relationship counseling, with the aim of addressing psychological and interpersonal issues that may be contributing to PE. Behavioral therapy involves physical techniques that have been developed to help men delay ejaculation. The "stop-start" technique involves the patient or his partner stimulating the penis until he feels the urge to ejaculate, then stopping until the sensation passes. Another behavioral therapy technique commonly employed involves the "squeeze" technique, where the patient squeezes the glans penis at the moment he feels the urge to ejaculate, until this sensation passes (Melnik et al., 2011). Randomized controlled trials evaluating these behavioral modifications demonstrated that these techniques can improve insertion-to ejaculation time and sexual satisfaction compared to controls. However, these studies have found that the addition of pharmacological therapies combined with behavioral therapies were better than either intervention alone (Cooper et al., 2015).

The serotonergic system is felt to act as a suppressor of ejaculation at the level of the hypothalamus (Porst, 2011) based on the anti-ejaculatory side effect of serotonin reuptake inhibitors (SSRIs) and other drugs that increase central activity of serotonin (Foreman et al., 1989). One of the most commonly associated side effect of SSRIs are delayed ejaculation and absent or delayed orgasm (Jannini et al., 2015), and these known side effects have been utilized in the off-label treatment of PE, in either on-demand doses or longer acting chronic courses.

Dapoxetine is a short acting SSRI developed specifically for the treatment of premature ejaculation (Dresser et al., 2006). In contrast to longer-acting SSRIs which can take 2 weeks or longer to reach steady state concentration (Hiemke & Härtter, 2000), dapoxetine has both a shorter time to onset and rapid elimination, with concentrations declining to <5% of peak value by 24 h (Modi et al., 2006). Further investigations have revealed dapoxetine to be a safe and effective treatment of PE (Porst et al., 2010), with mild side effects such as dizziness, nausea or diarrhea in 4–10% of patients (McMahon et al., 2011). Furthermore, men taking dapoxetine for PE have demonstrated no evidence of increased suicidal ideation or attempts, a side effect reported with other longer acting SSRI's (McMahon et al., 2011). With these attributes, dapoxetine has been approved and utilized for the treatment of PE in 50 countries worldwide (Pryor et al., 2006).

Longer-acting SSRIs such as paroxetine, fluoxetine, and sertraline, as well as the tricyclic antidepressant clonidine, may be utilized in the treatment of men with medication-refractory PE. Paroxetine exerts the strongest delay in ejaculation (Waldinger et al., 2004) when utilized in a daily dosing regimen. This regimen requires use 5–10 days prior to onset of effect, and an additional 2–3 weeks prior to full effect (McMahon et al., 2004). Similar to dapoxetine, these other SSRIs have been found to be safe and effective treatment for delaying ejaculation (Montague et al., 2004). Nausea, dry mouth, drowsiness and decreased libido are some common side effects of SSRI treatment, and long term use may be associated with weight gain and increased risk of developing Type 2 diabetes (Fava et al., 2000). Lastly, while the risk for suicidal ideation or suicide attempts has not been found to be increased

in non-depressed men on SSRIs for PE, there is a small increase in this risk in youths with depression on SSRIs (Khan et al., 2003). Therefore, caution is recommended in prescribing SSRIs to young adolescents with PE aged 18 or less.

Topical anesthetics can be applied to the penis prior to beginning intercourse, and can be applied with a condom or without. Residual topical anesthetics can also cause vaginal numbness, so men should be counseled to either wash clean any residual active topical agent or wear a condom during intercourse. Lidocaine/prilocaine cream (2.5 g) applied for 20 to 30 min prior to intercourse has been shown to increase latency time (Montague et al., 2004), with minimal side effects.

Immunotherapy Targeting Male Factor

Anti-sperm antibody (ASAB)-mediated male infertility is a rare cause of infertility, reported in 6–11% of infertility cases (McLachlan, 2002). However, when present, it is a potentially treatable cause. ASABs are felt to be formed in the epididymis, often in the presence of downstream obstruction (eg., vasectomy), infection/inflammation, or trauma. The IgG isotype is felt to be the most common, and important, of the isotypes seen. It appears that these Ab exert their effect in a variety of ways. Most think that they cause agglutination (sperm sticking together), thus inhibiting progressive forward motility, as well as clumping of the sperm in the cervical mucus. Others have reported reduced sperm viability due to cytotoxic ASABs, although this has been difficult to ascertain in vivo. Finally, impairment of the sperm-egg interaction has been demonstrated, with altered binding of the sperm to the zona pellucida. This has been demonstrated in conventional IVF. While there was also a theory of post-fertilization effects of ASABs, this has been disproven, as ICSI has been shown to be an effective treatment for ASABs, with no adverse effects on the fertilization rate or embryo development.

Diagnosis of ASABs is somewhat difficult, as they have been demonstrated in some fertile men. There are 2 methods for detection, direct and indirect. Direct methods identify ASABs on the sperm using anti-IgG antibodies. Indirect methods detect ASABs in body fluids (cervical fluid, blood, semen). The 2 most popular methods for direct testing are the immunobead test (IBT) and the mixed agglutination reaction (MAR). The strengths of the IBT are that the type of Ig, the percentage of sperm with beads attached and their location (head, mid-piece, tail) can be quantified. Reagent cost, time and non-specific binding are difficulties. Location of binding is important as well, as tail tip binding is of much less clinical significance than head or body binding. The MAR test methods uses latex beads or red blood cells labeled with human IgG A, M or G which are co-incubated with viable sperm following which anti-human Ig is added to cause agglutination with the sperm. Indirect testing is typically performed on the fluid in question using serologic tests to detect and quantify specific Ig isotypes.

The management of ASABs was previously difficult, as many treatments were empiric and anecdotal. However, with the advent of ICSI, most clinicians utilize this to overcome significant ASABs. There are situations; however, when couples are not open to IVF and wish to try medical therapy. There are 2 concepts used in the medical treatment of ASABs, either removal of the ASABs or suppression of their formation. The first method, removal, is rarely successful. ASABs bind to sperm prior to ejaculation; thus, attempts to wash them off are typically unsuccessful (they are bound by a nearly unbreakable covalent bond). Studies have explored prevention of ASAB formation through the use of immunosuppressive therapy. Most of these treatments utilize glucocorticoids, such as prednisone, in doses high enough to suppress the immune system, and are taken either cyclically or for several months. Unfortunately, the high rate of adverse events, particularly aseptic necrosis of the hip (reported in 1:150 cases), has limited the use of this treatment. One randomized study examined the use of immunosuppressive therapy with and without IUI and found the cumulative pregnancy rate with IUI to be 39% vs only 4% with timed intercourse. There were minimal side effects in this trial which used 40 mg of prednisone/day for 2 weeks, followed by 20 mg/day for 2 weeks (Robinson et al., 1995). While this report was promising, none of the couples had attempted IUI previously, thus bringing the impact of the steroid treatment into question. Thus, the utilization of ICSI has become the standard treatment for immunologic-mediated male infertility.

Conclusion

The non-endocrine medical treatment of male infertility has been hampered by the lack of randomized controlled trials for most of the conditions that it covers. Treatment of ejaculatory dysfunction is difficult and often results in the utilization of sperm retrieval with IVF. Similarly, the medical treatment of immunologic-mediated male fertility problems has not resulted in high success rates and ultimately results in the use of IVF/ICSI. While our understanding of many of the etiologies of male infertility is continually evolving, future medical therapy will likely be aimed at addressing the underlying causes.

Glossary

Asthenospermia Lower than normal sperm motility (<40% motile on analyses).

Azoospermia Semen abnormality in which no sperm is present in the ejaculate; to diagnose a patient as azoospermic, there must be no sperm in two separate semen analyses after centrifuged specimen is examined under a microscope.

Hypothalamus Portion of the brain that controls release of reproductive hormones. Releases gonadotropin-releasing hormone (GnRH) to stimulate the anterior pituitary gland to secrete luteinizing hormone (LH) and follicle stimulating hormone (FSH).

Idiopathic infertility Infertility in the absence of an identifiable cause.

Oligospermia Sperm concentration <15 million per mL.

Spermatogenesis Formation of sperm from germ cells located in the seminiferous tubule of the testicle.

Teratospermia Abnormal morphology of sperm (<4% sperm with abnormal form).

Introduction

Approximately 15% of couples are unable to conceive after 1 year of regular intercourse. It is estimated that the male at least contributes to the issue 50%–60% of the time, and is the sole cause in 20% of couples. Not infrequently, the male may have an abnormal semen analysis without an identifiable cause. In fact, in men with abnormal semen analyses parameters, the etiology is unknown around 25% of the time (Ko et al., 2012). In these instances, semen analyses will demonstrate decreased sperm counts, frequently associated with decreased motility and/or morphology. The ideal management of these individuals is not well defined (Kim and Schlegel, 2008). For the better part of the last century, varying medical treatments have been used off-label empirically despite the presence of mixed evidence supporting their use. A recent survey of 387 urologists found that approximately two thirds of providers utilized empiric medical treatment for idiopathic male infertility (Ko et al., 2012). The two main targets of modification include modification of the hypothalamic–pituitary–gonadal (HPG) axis and minimizing oxidative stress on spermatozoa. The objective of this chapter is to describe these treatments, the rationale for their use, and to summarize the evidence for and against them.

Hypothalamic–Pituitary–Gonadal Axis Modification

To adequately understand the rationale for the use of these empiric medications, it is necessary to briefly explain the control of reproductive hormones in the body, which are regulated via the HPG axis. Gonadotropin-releasing hormone (GnRH) is released in a pulsatile fashion from the hypothalamus and directly stimulates the anterior pituitary gland. In response, the pituitary gland releases luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which stimulates the production of testosterone and sperm in the testicle, respectively. Testosterone may be converted to estrogen, via a process catalyzed by aromatase. A negative feedback loop is in place, in which increased testosterone and thereby estrogen via aromatization, leads to a decrease in production of GnRH by the hypothalamus, and results in decreasing the release of LH and FSH (Kim and Schlegel, 2008). The empiric therapies discussed below involve manipulation of this cascade in some way.

Anti-estrogens

Perhaps the most prescribed and longest utilized forms of empiric therapy are the anti-estrogens, specifically clomiphene and tamoxifen. These medications are considered selective estrogen receptor modulators and function by blocking estrogen receptors, thereby inhibiting the negative feedback loop affecting production of GnRH by the hypothalamus. This serves to indirectly increase the secretion of LH and FSH by the anterior pituitary gland, with subsequent increases in testosterone and spermatogenesis. Unfortunately, the results of studies evaluating this effect in patients without hypogonadism have been mixed, with some demonstrating no benefit to treatment for idiopathic infertility and others having shown improved sperm counts and pregnancy rates (Kumar et al., 2006). Further, in a Cochrane database review of 10 studies analyzing around 740 patients on the effect of clomiphene and/or tamoxifen, there appeared to be a beneficial effect on testosterone, but there did not seem to be enough evidence to support their use for idiopathic infertility (Vandekerckhove et al., 2000). However, a more recent meta-analysis by Chua et al., which pooled

results from 11 randomized controlled trials employing either clomiphene or tamoxifen, demonstrated an odds ratio consistent with a 2.4 times greater chance of pregnancy, in addition to improvement in sperm concentrations and motility with anti-estrogens (Chua et al., 2013).

Use of anti-estrogens for idiopathic infertility remains off-label. Optimal dosing of these medications is not well established, however common doses administered are included in Table 1. Duration of therapy generally accounts for a spermatogenesis cycle of 74 days and studies suggest a large number of patients respond by 3 months, however some authors suggest treatment courses should not last longer than 12–15 months (Chebab et al., 2015). Clomiphene and tamoxifen are generally well tolerated by most patients. The most common side effects being gastrointestinal upset, dizziness, alopecia, gynecomastia, and weight gain. Additionally, it is important to note that some studies paradoxically demonstrate worsened sperm parameters with use, including decreased motility of sperm and worsened sperm counts. These improved with stoppage of the medication, although in a very small number the sperm counts remained decreased (Ramasamy et al., 2012).

Aromatase Inhibitors

Aromatase is an enzyme found in many locations in the body, including the testis and adipose tissue, which converts testosterone to estrogen. As mentioned previously, estrogen has an inhibitory effect on the hypothalamus in regards to production of GnRH via the negative feedback loop. Thus, by decreasing conversion of testosterone to estrogen, there should be an increase in androgen levels and spermatogenesis in the testis. This class of medications may be either steroidal or non-steroidal. The non-steroidal medications, including anastrozole and letrozole, tend to be more selective and therefore are more commonly used (Schiff et al., 2007). There is some evidence to suggest that the medication improves sperm parameters, however there is overall a dearth of high quality randomized controlled trials to support its use (Ramasamy et al., 2012). Intuitively, the medication would potentially be most effective in subfertile men with high estrogen levels.

As is the case with the anti-estrogens, aromatase inhibitor use is off-label for idiopathic infertility, and the ideal dosing regimen and duration is not well defined (Table 1). Frequently, the choice of an aromatase inhibitor versus an anti-estrogen is based off the ratio of testosterone to estrogen (T:E) in a patient. Specifically, aromatase inhibitors would be considered as therapeutic options in patients with higher estrogen levels and a T:E ratio of < 10 (Barazani et al., 2016). Side effects are infrequent, but can consist of transient elevations of liver enzymes and changes in libido. Long term, there may be a risk of osteopenia secondary to estrogen deficiency (Schiff et al., 2007).

Androgens

Androgens are known to play a central role in male sexual function and infertility, having demonstrated that testosterone encourages spermatogenesis. Furthermore, 20%–30% of male infertility patients are estimated to have low levels of testosterone (Ring et al., 2016). Perhaps intuitively, one could then infer that administration of exogenous testosterone could benefit semen parameters. However, due to the aforementioned negative feedback loop, exogenous testosterone actually serves to suppress the levels of intra-testicular testosterone, leading to azoospermia (Kim and Schlegel, 2008). Some investigators noticed that there seemed to be an increase in sperm counts after cessation of androgens, leading to theories that there may be some therapeutic utility of testosterone utilizing this “rebound effect” to treat male infertility. However, in meta-analysis and randomized controlled trials, this effect was not born out (Kumar et al., 2006). Thus, there is no role of androgen monotherapy in male infertility. Despite this, in a recent survey, around 25% of urologists reported prescribing testosterone for male infertility treatment, highlighting the need for increased education regarding empiric therapies for both patients and providers alike (Ko et al., 2012).

Table 1 Medications and commonly used dosages

Class	Medication	Dosage	Notes
Anti-estrogens	Clomiphene citrate	25 or 50 mg PO daily	Dose ranges used variable, reported from 12.5 to 400 mg. Intervals also vary and can include every other day dosing along with 25 day cycle followed by a 5 day break.
	Tamoxifen citrate	10–30 mg PO daily	Some controlled studies showed no effect with 10 and 20 mg doses
Aromatase inhibitors	Anastrozole	1 mg PO daily	Ideal frequency of administration unclear; ranges from weekly to daily
	Letrozole	2.5 mg PO daily	
Gonadotropins	hCG	1500 u SQ/IM 3 × per week	Can increase to 3500 u 3 × per week
	hMG	75 u IM 3 × per week	Titrate to 150 u if do not see response in sperm counts
	Recombinant human FSH (r-h FSH)	150 IU SQ two to three times per week	Can increase by 75 IU if no sperm present after 6 months

Gonadotropins

As described above, FSH and LH secreted by the anterior pituitary gland stimulate sertoli cells and leydig cells, respectively to produce sperm and testosterone. Thus it is postulated that abnormalities in gonadotropin secretion could contribute to male infertility. In fact, gonadotropins are the only FDA approved medication for male infertility, although specifically in situations of low FSH/LH and testosterone, known as hypogonadotropic hypogonadism (Chebab et al., 2015). Various analogues of exogenous FSH, LH, and pulsed GnRH exist. Common regimens are listed in Table 1. Typically, hCG (human chorionic gonadotropin, an LH analogue) monotherapy is the first line of treatment as this is more cost effective. hCG can lead to a dramatic increase of intra-testicular testosterone and therefore may be the only medication necessary to stimulate sperm production. If ineffective, analogues of FSH, either human menopausal gonadotropin (hMG) or recombinant human FSH (rh-FSH) can be used in addition to hCG (Chebab et al., 2015). hMG contains a mixture of LH and FSH purified from human urine and therefore has a theoretical concern about infection. The advantage of this medication is cost, as the recombinant product, which contains pure FSH, is significantly more expensive. In 2005, Foresta et al. analyzed the use of rh-FSH for 3 months on men with idiopathic oligoasthenozoospermia and in a sub group analysis found a benefit to sperm parameters and unassisted pregnancy rates (Foresta et al., 2005). Additionally, in 2013, a Cochrane review of six randomized controlled trials including around 450 patients seemed to suggest a benefit in live births and spontaneous pregnancy rates, although concluded that, while encouraging, more evidence was ultimately necessary (Attia et al., 2013).

Gonadotropin Releasing Hormone Therapy

Studies investigating the pregnancy rates in couples with men treated with pulsatile GnRH (5–20 mg per pulse every 2 h) for idiopathic oligoasthenoterazoospermia failed to demonstrate improvement over controls and given the high cost of this therapy it is seldom used clinically (Cocuzza and Agarwal, 2007).

Antioxidant Therapy

Reactive oxygen species (ROS), have long been a postulated target mechanism of male infertility and given the large amount of polyunsaturated fat in their cell membrane, spermatozoa are especially susceptible to damage via ROS as they have low levels of intracellular antioxidants and DNA repair enzymes. Therefore it is the antioxidant capacity of the semen that has been thought to be the protectant with antioxidant carotenoids, carnitine, folate, selenium, vitamin E, vitamin C, and zinc all being found in semen. There is evidence that infertile men have higher levels of ROS in their semen (Showell et al., 2014). These observations have led to interest in antioxidant treatment for male infertility. There are several studies that support the idea that antioxidants may improve the DNA integrity and function of sperm, although the exact mechanism of action and ideal regimen of supplementation is not well defined (Ramasamy et al., 2012). A Cochrane Review by Showell in 2014 concluded that with low quality evidence, antioxidants might have been effective in treating men with subfertility, as pregnancy rate and live birth rate were both improved but called for better evidence. What follows is a brief description of available supplements and the evidence supporting their use. In general, although further high quality studies are necessary, the side effects of these supplements are minimal, if any, and antioxidants are commonly used as an adjunct for empiric medical treatment of infertile males (Schiff et al., 2007).

Vitamin C

Vitamin C (or ascorbic acid) is a water-soluble antioxidant found in high concentrations in seminal plasma. It is postulated that it may limit oxidative DNA damage by neutralizing free radicals and protecting cell membrane degradation against ROS. Some studies have found seminal concentrations of vitamin C to correlate positively with sperm concentration and negatively with ROS. Further, vitamin C supplementation may decrease the level of DNA damage in sperm, although this has not definitively been shown to lead to improved semen parameters or pregnancy rates (Ahmadi et al., 2016; Agarwal and Sekhon, 2010).

Vitamin E

Vitamin E (α -tocopherol) is a lipophilic antioxidant usually found in cell membranes that is believed to inhibit ROS while enhancing the activity of other antioxidants. In fact, some randomized controlled trials did suggest a benefit in infertile males with high ROS levels, although others have found no improvement in semen parameters (Ahmadi et al., 2016; Agarwal and Sekhon, 2010).

Carnitine

Mostly obtained through diet, carnitine has been found to fend off ROS induced damage to cell membranes and DNA in sperm. In addition to its antioxidant properties, it is believed that carnitine plays a role in sperm maturation via enhancement of energy production, and therefore motility (Kumar et al., 2006). The highest concentrations of the compound exist in the epididymis.

Data exists to support the idea carnitine supplementation may improve semen motility, particularly in men with lower sperm motility at baseline. Some other studies have suggested that it may improve concentrations as well, although once again results have been somewhat mixed (Ahmadi et al., 2016).

Coenzyme Q10 (CoQ10)

CoQ10 functions in cellular respiration and energy generation. While its exact role in the treatment of male infertility is not entirely clear, it is postulated that it may lead to greater energy for mitochondria in sperm resulting in increased motility, and may scavenge free radicals and inhibit the formation of hydroperoxide, a ROS. Most studies on CoQ10 do show an improvement in semen parameters, although this did not necessarily lead to increased pregnancy or live birth rates (Ahmadi et al., 2016).

Zinc

The second most common metal in the body after iron, zinc has been shown to protect sperm from bacteria and chromosomal damage, as well as play a role in testicular development and maturation of sperm. For example, deficiency of zinc is associated with hypogonadism and incomplete sexual development in humans. There are several controlled and blinded studies that show an increase in sperm counts with zinc supplementation (Ahmadi et al., 2016).

Selenium

Selenium is necessary for development of the testicles and may protect against DNA damage in sperm, although the exact mechanism is unclear, although it is believed they play a role in maintain the structure of sperm. In fact, selenium deficiency may lead to worsening sperm morphology and motility. Some data suggests selenium, when combined with other supplements, may lead to improved motility and other parameters (Agarwal and Sekhon, 2010).

Glutathione/*N*-Acetyl Cysteine

Glutathione, as the most common non-protein thiol in the body, serves to scavenge ROS in sperm. Fertile men have been found to have more glutathione in their semen, and some data suggests worsening motility and morphology of sperm with low levels of glutathione. Its precursor, *N*-acetyl-cysteine (NAC), may be used as a supplement to augment the production of glutathione, and may have antioxidant properties itself. One study did find improved sperm concentration when NAC was given with selenium (Agarwal and Sekhon, 2010; Kumar et al., 2006).

Conclusion

As mentioned above, in a not insignificant cohort of men diagnosed with male factor infertility, no medically or surgically correctable etiology is identified. In these cases, it is reasonable to consider empiric medical treatment. The aims of this therapy are either to stimulate the HPA axis or prevent free radical damage to spermatozoa. These medications are generally well tolerated, and have been used for nearly half a century by many providers. It is important to note once again that Food and Drug Administration approval does not exist for the specific indication of male infertility for many of the medications. Further, despite a lack of large, high quality studies supporting their efficacy, empiric medical treatment is generally considered safe and reasonably priced means of improving ones odds of conception. As previously mentioned, the ideal patient to benefit from empiric treatment is not well defined. However, a recent study found that a nomogram based on body mass index, age, LH, as well as change in serum testosterone after initiating treatment could be predictive of a positive response to sperm counts using medical therapy (Barazani et al., 2016).

In conclusion, while further studies are necessary, empiric treatment is commonly used and may be beneficial to some men with idiopathic infertility. Patients should have informed discussions with their providers regarding the potential benefits and risks of the medications prior to use as well as discussions regarding proceeding with other forms of assisted reproductive techniques when no pregnancy is seen after reasonable trial period.

Nutraceutical Therapy in Male Infertility

Pratik Kanabur and Ranjith Ramasamy, University of Miami, Miami, FL, United States

© 2018 Elsevier Inc. All rights reserved.

Background

Overview

Global rates of male infertility range from 2.5% to 12%. Males are found to be solely responsible for 20%–30% of infertility cases and contribute to 50% of cases overall (Jungwirth et al., 2012). The management of male infertility includes assessing and identifying a patient's potential health problems. Decreased general health status has been associated with lower sperm concentration, lower total testosterone levels and higher follicle-stimulating hormone values. Specifically, nutrition and lifestyle factors, which are currently huge public health issues, play a critical role in the normal function of the reproductive system. Aside from evident factors such as smoking (Saleh et al., 2002) and heavy alcohol consumption (Condorelli et al., 2015), male obesity and high fat diets (Taha et al., 2016) have also been implicated in male infertility. One of the leading hypotheses for pathophysiological explanation for idiopathic male infertility is damage to the reproductive tract due to oxidative stress from reactive oxygen species (ROS). Studies say that anywhere from 30% to 80% of male factor infertility are due to damaging effects of oxidative stress (Ko et al., 2014).

Reactive Oxygen Species and Reactive Nitrogen Species

ROS represent a broad category of molecules that indicate the collection of radicals and nonradical oxygen derivatives. These molecules have an unpaired electron in their outer orbit, and thus are highly reactive and interact with a variety of lipids, proteins, and nucleic acids in the body (Agarwal et al., 2008). Free radicals include superoxide, hydroxyl radical, and hydroperoxyl. Nonradicals include hydrogen peroxide, singlet oxygen, iron oxygen complexes, and hypochlorite. A subclass of ROS is reactive nitrogen species (RNS) such as nitric oxide and peroxynitrate. These molecules, which are prominent in different areas of the male reproductive system, are responsible for contributing to nitrosative stress. RNS have multiple physiologic functions, which include regulation of multiple signaling pathways, assembly of the tight junctions in the blood testis barrier, production of hormones, and maintenance of vascular tone. Specifically RNS also are essential for conducting various sperm functions such as capacitation, acrosomal reaction, zona pellucida binding, as well as sperm motility, morphology, and viability (Doshi et al., 2012).

Mitochondria's Role in ROS

The mitochondria are responsible for balance of reactive oxygen species. Along with production of ATP, initiation of apoptosis, production of heat, and hereditary contribution, mitochondria produce ROS during the formation of superoxide in the electron transport chain. In sperm, 25–75 mitochondria are arranged in tubular structures in the mid piece and are responsible for sperm motility and overall functionality. Thus an intact mitochondrial genome and metabolome is essential for sperm functionality. While a controlled level of ROS is necessary, an imbalance between ROS and ROS scavenging by seminal antioxidants results in seminal oxidative stress which may lead to a decrease in motility, abnormal sperm morphology, and decreased ATP production leading to overall decreased sperm viability as well as increased sperm DNA damage (Amaral et al., 2013).

Sources of ROS

Human semen consists of different types of cells such as mature and immature spermatozoa, round cells from different stages of the spermatogenic process, leukocytes and epithelial cells. Of these, leukocytes (neutrophils and macrophages) and immature spermatozoa are the two main sources of ROS. ROS come from multiple extrinsic and intrinsic sources in the semen. Intrinsic sources include activated leukocytes from inflammation (i.e., diabetes, renal failure) and infection, immature spermatozoa with abnormal morphology, and varicoceles, which are abnormal dilations of the veins in the testicles. Extrinsic sources include smoking, alcohol, obesity, radiation exposure, and other environmental toxins such as pesticides, heavy metals, and plastics (Agarwal et al., 2016). These exposures are summarized in Table 1.

ROS and Male Infertility

In 30%–40% of cases, no male-infertility-associated factor is found. However, even in these cases of idiopathic normozoospermic male factor infertility, up to 25% of men have significantly higher levels of ROS when compared with fertile controls (Zini and Al-Hathal, 2011). In addition, the decreased levels of antioxidant capacity found in this population further synergize this state of oxidative stress. The delicate balance of oxidation and reduction is required for all major sperm functions such as capacitation, hyperactivation, and sperm-oocyte fusion; ROS may also disrupt sperm by fragmenting its DNA and interfering with normal chromatin packing. Normal chromatin compaction is required for sperm maturation during epididymal transit, capacitation, hyperactivation, acrosomal reaction, and sperm-oocyte fusion reaction, all of which are necessary for successful fertilization. Supraphysiologic ROS levels can affect sperm structural and functional integrity including motility morphology, count and viability. It can

Table 1 Sources of ROS

Category	Exposure	Results
Lifestyle	Smoking	Decrease in sperm motility and normal morphology
	Alcohol	Decrease in sperm concentration, motility, and normal morphology
	Obesity/high fat diet	Decrease in sperm concentration, motility, normal morphology, and vitality
Environmental	Air pollution	No significant changes in ejaculate volume, sperm concentration, motility, or normal morphology
	Pesticides	Decrease in sperm motility and normal morphology and an increase in pH of seminal fluid
	Plastics	Decrease in sperm concentration, motility, and normal morphology
Infection	Genitourinary	Decrease in sperm concentration
	Systemic	HIV: Leukocytospermia (increased white blood cells → increased ROS) and decreased sperm motility
		HBV: Decrease in ejaculate volume, sperm concentration, motility, vitality, and a decrease in pH of seminal fluid
Testicular	Varicocele	Decrease in sperm concentration
	Cryptorchidism	Decrease in sperm concentration, motility, normal morphology, and vitality
Chronic disease	Diabetes	Decrease in ejaculate volume
	Renal failure	Decrease in sperm concentration and motility
	Thyroid dysfunction	Hypothyroidism associated with statistically significant decrease in sperm concentration, motility, and normal morphology
Medications		Hyperthyroidism associated with statistically significant decrease in sperm motility
	Opioids	Decrease in sperm concentration, motility, and normal morphology
	SSRI	Decrease in sperm motility and normal morphology

induce apoptosis, resulting in low sperm counts characteristic of men with idiopathic infertility. Sperm DNA damage may also decrease fertilization rates, reduce implantation, impair embryonic development, and increase miscarriage/pregnancy loss and the potential for birth defects.

The spermatozoa and seminal plasma contain multiple protective antioxidants to protect spermatozoa from oxidative stress by scavenging the free radicals. These include both high molecular weight enzymatic antioxidants (superoxide dismutase, catalase and glutathione peroxidase) as well as nonenzymatic antioxidants (ascorbic acid, α -tocopherol, pyruvate, glutathione, L-carnitine, taurine, and hypotaurine)—which provide the bulk of antioxidant activity.

Nutraceutical Therapy

Overview of Nutraceuticals

Nutraceuticals are products derived from food that have health benefits, and may include amino acids, isolated nutrients, or dietary supplements. Many of these products have antioxidant properties and can help scavenge ROS. Since seminal oxidative stress may be due in part to deficiency in seminal antioxidants and there is a lack of serious side effects related to antioxidant therapy, nutraceutical therapy may be used in men with clinical subfertility, as well as in men with normal semen parameters who have been unable to conceive for 6–12 months.

Specific Nutraceuticals

Many different antioxidants have been investigated in the literature. It is important to distinguish between enzymatic antioxidants such as superoxide dismutase, catalase, and glutathione peroxidase and nonenzymatic antioxidants such as vitamins, proteins, glutathione, and ubiquinol. The different nutrients and their respective key role in infertility are summarized in [Table 2](#). Some of the important antioxidants studied in literature are discussed below. Overall, research has demonstrated that a decrease in the seminal levels of these antioxidants is associated with infertility. In addition, when given to men with infertility, these supplements or nutraceuticals can improve semen parameters.

CoEnzyme Q-10

CoEnzyme Q-10 (CoQ10) is an antioxidant molecule and a component of the mitochondrial respiratory chain, which participates, in aerobic cellular respiration. It plays an important role in energy metabolism, as well as functioning as a liposoluble chain-breaking antioxidant for cell membranes and lipoproteins ([Gvozdjaková et al., 2015](#)). At the cellular level, CoQ10 exists as a redox pair, that is, it is found in two forms—ubiquinone, the oxidized form, and ubiquinol, the reduced form—which are constantly switching back and forth as CoQ10 transfers a hydrogen in the electron transfer chain in the mitochondria. As a supplement there is no difference in taking ubiquinone or ubiquinol. Specifically, ubiquinol, which is the reduced state of CoQ10 is a strong lipophilic antioxidant that can regenerate other antioxidants. Ubiquinol inhibits organic peroxide formation in both the seminal fluid and seminal plasma, which reduces the oxidative stress to which sperm cells may be subjected ([Mancini and Balercia, 2011](#)). Thus

Table 2 Different nutraceutical therapies and role in infertility

<i>Ingredient</i>	<i>Key role in infertility</i>
Co-Enzyme Q-10	Energy, antioxidant, sperm parameter benefits
L-Carnatine	Energy, sperm parameter benefits
Lycopene	Antioxidant, sperm parameter benefits
Beta carotene	Antioxidant
Vitamin C	Antioxidant
Vitamin E	Antioxidant
Methylcobalmin	Sperm parameter benefits
Astaxanthine	Sperm parameter benefits
Alpha lipoic acid	Antioxidant
Zinc	Sperm parameter benefits
Selenium	Antioxidant

there is a strong positive correlation between CoQ10 concentration and sperm count and motility. Three clinical trials, summarized in a metaanalysis by Lafuente et al. have shown that supplementing infertile men with CoQ10 improved sperm concentration, motility, and concentration in the seminal plasma (Lafuente et al., 2013). However, this is no reported data on live births after treatment. Thus supplementation with CoQ10, while has not been proven to help increase pregnancy rates, has been shown to improve semen parameters.

L-Carnitine

L-Carnitine is a molecule that is necessary for beta-oxidation of fatty acids in the mitochondria and helps to continue the energy supply through the transfer of fatty acids from cytosol to mitochondria. It also protects DNA and cell membranes from the damage caused by ROS (Agarwal and Said, 2004). The highest concentration of L-carnitine in the human is in the epididymis, with the concentration being 2000 times greater than that in serum and infertile men have been found to have lower levels of seminal L-carnitine. Supplementation of L-Carnitine in infertile men demonstrated an improvement in sperm concentration, mobility, viability, and morphology (Sofimajidpour et al., 2016). In a metaanalysis by Zhou et al., supplementation with L-carnitine or L-acyl-carnitine versus placebo led to a significant improvement in pregnancy rate and sperm motility but not total sperm concentration or atypical sperm forms (Zhou et al., 2007). In addition, one study showed that in men with a grade 2 varicocele, which are varicoceles that are palpable on clinical examination, men who chose between 250 mg L-carnitine four times a day for 6 months or varicocelectomy showed improvement in sperm concentration, motility, and morphology similarly in both groups (Sofimajidpour et al., 2016).

Lycopene

Lycopene is a compound from the carotenoid family obtained through consumption of red-colored fruits and vegetables (Gajowik and Dobrzyńska, 2014). It is found in higher concentrations in semen and the concentration of lycopene was significantly decreased in infertile men (Ghyasvand et al., 2015). Lycopene is a lipophilic molecule that incorporates in the cell membrane to protect the sperm by preventing lipid peroxidation and also neutralizing ROS (Gajowik and Dobrzyńska, 2014). Studies have shown that supplementation with lycopene improved oxidative stress parameters such as DNA fragmentation index and sperm related parameters including sperm count, motility, and concentration. It did not, however, improve sperm morphology (Agarwal et al., 2014).

Vitamin E

Vitamin E is a major chain-breaking antioxidant in sperm membranes and this effect appears to be dose dependent. Naturally occurring vitamin E is actually a mixture of four tocopherols (alpha, beta, gamma, and delta) and four tocotrienols (again, alpha, beta, gamma, and delta). Most vitamin E supplements consist solely of a synthetic form of pure alpha tocopherol. Vitamin E scavenges the three major types of free reactive species, namely superoxide, hydrogen peroxide, and hydroxyl radicals (Kobori et al., 2014). In a randomized, double blind, placebo-controlled trial by Kessopoulou et al., in vitro functional tests of human spermatozoa improved after 3 months of alpha-tocopherol (600 mg/day) therapy (Kessopoulou et al., 1995). In another study by Suleiman et al., treatment with alpha-tocopherol reduced levels of malondialdehyde, a marker of lipid peroxidation, and 11 out of the 52 (26%) men treated were able to impregnate their spouses and 9 of those ended up in live births (Suleiman et al., 1996). While many studies have demonstrated a potential role for vitamin E in the management of male infertility, another randomized trial by Rolf et al. who used both 800 mg vitamin E and 1000 mg vitamin C failed to confirm these findings (Rolf et al., 1999).

Vitamin C

Vitamin C is another important chain-breaking antioxidant and is present at a higher concentration in seminal fluid than in plasma as well as being present in low but detectable amounts in sperm cells. Vitamin C neutralizes hydroxyl, superoxide, and hydrogen peroxide reactive species and prevents sperm agglutination, while preventing lipid peroxidation, recycling vitamin E, and protecting against DNA damage induced by hydrogen peroxide radicals (Angulo et al., 2011). It has been suggested that oral administration of

vitamin C with vitamin E significantly reduces hydroxyguanine levels in spermatozoa and also leads to an increased sperm count (Kobori et al., 2014; Rolf et al., 1999)

Zinc

Zinc is second only to iron as the most abundant element in human tissues. Although Zn is found in most types of foods such as red meat, white meat, fish, and milk, the World Health Organization estimates that one-third of the world's population is deficient in zinc. Zinc and citrate are excreted from the prostate gland as a low-molecular-weight complex; thus, it is estimated that the zinc levels in seminal plasma typically represent prostatic secretory function (Zhao et al., 2016). Since zinc is found in high concentrations of seminal fluid, it has numerous important functions, and it is essential for conception, implantation, and a favorable pregnancy outcome. On a more molecular level, zinc influences the fluidity of lipids and, thus, the stability of biological membranes. Zinc is a co-factor for superoxide dismutase, one of the important enzymatic antioxidants found in the semen. It also helps stabilize sperm chromatin. Lastly zinc has been found to play a regulatory role in the process of capacitation and the acrosome reaction (Gavella and Lipovac, 1998). Studies on the curative effects of zinc with respect to male infertility have shown that zinc supplementation can significantly increase the percentage of normal sperm morphology, sperm motility and semen volume. However, there were no significant effects of zinc supplementation on the sperm viability, sperm concentration, sperm count or percentage of abnormal sperm morphology (Zhao et al., 2016).

Selenium

Selenium (Se) is an essential element for normal testicular development, spermatogenesis, and spermatozoa motility and function. The predominant biochemical action of Se in both humans and animals is to serve as an antioxidant via the Se-dependent enzyme glutathione peroxidase and thus protect cellular membranes and organelles from peroxidative damage. In one study, infertile men with idiopathic asthenoteratospermia were treated with 200 µg of selenium with 400 U of vitamin E for at least 100 days. There was a 53% improvement in sperm motility, morphology, or both and an 11% spontaneous pregnancy rates in comparison with no treatment (Gavella and Lipovac, 1998). In another placebo controlled clinical trial carried out in Iran and Tunisia, selenium supplementation improved sperm counts, concentration, motility and morphology as well as sperm concentration in infertile men (Gavella and Lipovac, 1998).

N-Acetylcysteine

N-Acetyl cysteine is a naturally occurring compound, which comes from amino acid L-cysteine, and functions as a precursor of glutathione peroxidase. One study investigated the effect of selenium and N-acetyl-cysteine on infertile men with idiopathic oligo-asthenoteratospermia. These men were treated with the combinational therapy for 30 weeks. All semen parameters significantly improved with selenium and N-acetyl-cysteine treatment (Gavella and Lipovac, 1998).

Overall Effects of Nutraceuticals

Dosages(Ko and Sabanegh, 2014)

Although the doses that are prescribed vary between physicians and different sources, review of literature revealed a range of dosages that are recommended for various nutraceuticals (Table 3).

Cochrane review on overall effects of antioxidants (Showell et al., 2017)

The Cochrane review was a large literature review of multiple studies, aimed to quantify the effect of nutraceutical therapies on sperm motility, sperm count, and ability to achieve a pregnancy and/or a live birth. The results are summarized in Table 4.

Table 3 Doses of various nutraceuticals

<i>Supplement</i>	<i>Daily dose</i>
Vitamin E	300–1000 IU
Carnitines	1–2 g/day
Zinc	40 mg/day
CoEnzyme Q10	200–300 mg
N-Acetylcysteine	600 mg
Vitamin C	1000 mg
Vitamin D	1000–4000 IU
Selenium	60–400 µg
Glutathione	600 mg
Lycopene	10–30 mg

Table 4 Review on effects of various antioxidants

<i>Fertility improvement</i>	<i>Antioxidants used</i>	<i>Findings</i>
Live birth rate	Vitamin E; zinc	Increased
Pregnancy rate	L-Carnitine, L-acetytyl carnitine, co-enzyme Q10, magnesium, vitamin E plus vitamin C, zinc, combined antioxidants	Increased
Sperm DNA fragmentation	Vitamin E plus vitamin C	Decreased
<i>Sperm concentration</i>		
- < 3 months	Docosahexaenoic acid, magnesium, vitamin C plus E, <i>N</i> -acetylcysteine, pentoxifylline, L-carnitine	No difference
- 6 months	L-Carnitine, selenium, <i>N</i> -acetylcysteine, CoEnzyme Q10, pentoxifylline	Increased
- 9 months or more	L-Carnitine, CoEnzyme Q10	Increased
<i>Sperm motility</i>		
- 3 months or less	Vitamin C, vitamin E, L-carnitine, selenium, <i>N</i> -acerylcysteine, magnesium, zinc, docohexamandic acid, pentoxifylline	No difference
- 6 months	L-Carnitine, selenium, <i>N</i> -acetylcysteine, CoEnzyme Q10, vitamin E	Increased
- 9 months or more	L-Carnitine, L-acetylcarnitine, CoEnzyme Q10	Increased

Adverse effects(Arcaniolo et al., 2014)

Even though nutraceuticals are benign products, excess intake can lead to adverse effects. Review of the literature revealed various adverse effects from excess intake of nutraceuticals. Since men often take these medications for an extended period of time, it is important to ensure that the dosages are not large enough to cause adverse effects (Table 5).

Treatment**Ideal Couple**

Ideal couple should want to attempt natural conception or intrauterine insemination. For patients that want to proceed with intra cytoplasmic sperm injection or in vitro fertilization, surgical therapy may be preferred over administration of nutraceutical therapy.

Female Considerations

Full female workup should be considered. Female lab values should be within normal limits. This includes a normal AMH, a normal day 3 FSH, good follicle count. An anatomical workup with a hysterosalpingogram should be normal as well.

Male Considerations

Nutraceutical therapy is primarily intended for the 30%–40% of infertile men where no cause could be determined (idiopathic infertility). According to EAU Guidelines on male infertility, there is little evidence for empiric treatment using naturaceuticals. However, medical therapy should be reserved only in men with hypogonadotropic hypogonadism, which is low gonadotropins and sex steroid hormone levels in the absence of any problems in the hypothalamic-pituitary-gonadal axis.

Male sperm count should be between 5 and 15 million/cm³, which is an intermediate range of sperm. A patient is considered to have oligospermia with a concentration < 5 million/cm³. On the other hand a normal sperm count is > 15 million. Thus for men with sperm count that is decreased but not enough to be considered as oligospermia, nutraceutical therapy should be considered.

Sperm motility should be < 40% but > 20%. Sperm motility is more important for natural conception or intra uterine insemination but not as important for artificial techniques.

Male should also have no other correctible causes of abnormal semen parameters. These include varicoceles, cryptorchidism, infection, and inflammation. In general a male with idiopathic oligoasthenozoospermia is an ideal candidate for nutraceutical therapy. Overall these men who choose to take nutraceutical therapy will need to do so for over 6 months at the dosages required. The end goal of treatment with nutraceutical therapy is to help increase the motility of the sperm.

Conclusion

This article provides an overview of various causes of seminal oxidative stress, use of specific nutraceutical therapies to help in men with idiopathic infertility, and the selection of an ideal couple for nutraceutical therapy. The causes of oxidative stress include but are not limited to lifestyle, drugs, infections, chronic diseases, and iatrogenic causes. Various nutraceuticals have been studied in literature and include CoEnzyme Q10, carnitine, lycopene, vitamin E, vitamin C, zinc, and selenium. In a review of the literature

Table 5 Adverse effects on increased intake of various nutraceuticals

Supplement	Reported adverse effects
Vitamin E	GI distress, fatigue, muscle weakness, headache blurry vision, rash, bruising, bleeding complication (> 800 IU/d) Cardiovascular complications (> 400 IU/d)
Vitamin C (> 2000 mg/d)	Dyspepsia, headache, increased risk of nephrolithiasis
Vitamin A (> 50,000 IU/d)	Fatigue, irritability, mental status change, visual disturbances, vertigo Anorexia, GI distress, excessive sweating, myalgia/arthritis
Arginine	Hepatotoxicity, hypoplastic, anemia GI discomfort, hypotension, electrolyte abnormalities, renal insufficiency
Carnitine (> 4 g/d)	Increased bleeding risk, elevated glucose levels, worsening symptoms of sickle cell disease, asthma
CoEnzyme Q10	GI distress, seizures, malodorous body secretion
Glutathione	GI distress, loss of appetite, headache, skin rash
N-Acetyl-cysteine	Not adsorbed within GI tract GI distress, rash, fever, headache, drowsiness
Selenium	Hypotension, hepatic toxicity GI distress, nail changes, fatigue, irritability, hair loss, garlic breath/odor
Zinc	Metallic taste, muscle tenderness, tremors, facial flushing, hematologic changes, hepatic, and renal insufficiency
(> 200 mg/d)	GI distress, loss of appetite, dehydration, gastric ulceration, rash; headache
(> 450 mg/d)	Altered iron function, low copper levels, sideroblastic anemia, reduced immune function, reduced HDL levels

on nutraceutical therapies, it was found that taking these various supplements for over 6 months at certain doses increases chance to improve sperm count and motility. Overall, an infertile man with oligoasthenozoospermia is the best candidate for nutraceutical therapy.

Acupuncture

In 1997, the National Institutes of Health (NIH) published a consensus statement stating that acupuncture is a promising modality for treating a wide range of conditions and that there was sufficient scientific evidence to subsidize the incorporation of acupuncture therapy into conventional medicine (Crimmel et al., 2001).

A fundamental concept in Chinese medicine is that two opposite but complementary forces (Yin and Yang) lie behind all natural phenomena and disease is considered the result of disharmony or imbalance of those forces. Acupuncture is part of traditional Chinese medicine, and its theory is based on the hypothesis that there are patterns of energy flow (Qi) through the body that are essential for health. The goal of acupuncture is to correct imbalances of the Qi and restore health through manual or electrical stimulations of needles inserted at points along the meridians that represents organs of the body. Another type of stimulation is moxibustion, which involves in the burning of the artemisia wool over specific points.

In the last decade of the past century, there were three controlled studies that showed promising results, but unfortunately, they were uncontrolled trials. In 1992, Gerhard et al. (Gerhard et al., 1992) reported mild but statistically significant improvement in sperm motility that was evident up to 10 weeks after the completion of acupuncture therapy. Progressive motility increased from 21% to 26% and total motility increased from 42% to 50%. Minghua (1993) reported a significant improvement not only in motility but also in sperm density. Sperm motility improved from 37% to 61% after acupuncture therapy. In 1997, Siterman et al. (1997) reported improvements in sperm viability and total motile sperm count (from 8.5 million to 19.3 million after 5 weeks of acupuncture therapy). Unfortunately, these studies did not encompass post-therapy evaluation up to or beyond the 90-day period needed for the maturation of spermatogonia to ejaculated spermatozoa.

In a prospective controlled study, Pei et al. (2005) reported a statistically significant improvement in the ultrastructural integrity of spermatozoa in 28 patients that receive acupuncture twice a week for 5 weeks. In another prospective controlled study, 19 patients with primary infertility with semen abnormalities were randomized into two groups that received acupuncture and moxibustion. The patients in the treatment group were stimulated at therapeutic points, while patients in the control group were stimulated at nontherapeutic points twice a week for 10 weeks. The authors reported a significant increase in the percentage of sperm with normal morphology (Gurfinkel et al., 2003). Dieterle et al. conducted a study where patients were randomized to receive either acupuncture or placebo acupuncture twice a week for 6 weeks. Placebo acupuncture was administered with non-penetrating needles in the same points used to manipulate the treated patients. The authors reported a significant effect of acupuncture on the percentage of total motile sperm (Dieterle et al., 2009).

A recent systematic review and metaanalysis that searched relevant studies in English, Korean and Chinese databases, including four randomized clinical trials (Dieterle et al., 2009; Liu et al., 2011; Wang et al., 2008; Shi, 2009) that compared acupuncture treatment against placebo, sham or no treatment, concluded that the acupuncture treatment might significantly improve the sperm motility and sperm concentration in infertile men with poor semen quality. However, there was no significant impact on the pregnancy rate (Jerng et al., 2014).

The underlying mechanism by which acupuncture improve the sperm parameters is yet to be determined. One possible role of acupuncture relies on the fact that it stimulates somatic afferent nerves and possibly modulates the autonomic nervous system and controls the hypothalamus-pituitary-gonadal axis (Franconi et al., 2011). Another possible factor is due to higher testicular blood flow in patients submitted to electroacupuncture, with possible increase in seminal antioxidant agents (Cakmak et al., 2008).

Herbal Medication

Herbal medications are a foundation of traditional Chinese medicine for male infertility. In the majority of cases, herbal formulas are prescribed as a decoction that may consist of a dozen or more individual ingredients. As most studies were published in the Chinese medical literature, the outstanding review and translation by Jiang and colleagues was used as a guide (Jiang et al., 2017).

Zhang et al. investigated the effect of Bushen Shengjing Decoction in 82 patients with azoospermia or severe oligospermia combined with intracytoplasmic sperm injection (ICSI) compared to 82 patients submitted to ICSI alone as controls. It was found that sperm density, sperm motility, sperm morphology, fertilization rate, and clinical pregnancy were higher in the treatment group, suggesting that Bushen Shengjing Decoction helped decrease semen ROS levels and improve sperm quality (Zhang et al., 2007).

In an effort to study the effect of herbal formula WuziYanzong Pill, Wang et al. divided 231 patients in three different groups: the first received only the herbal formula, the second was submitted to acupuncture alone, and the third received both treatments. There was an increase in sperm density, sperm vitality, and in the acrosome enzyme activity compared to pretreatment, with a more obvious improvement in the combined therapy group (Wang et al., 2008).

Several other studies with different types of herbal preparations have been reported. Sun et al. showed that herbal formula QingreYulin Decoction has antibiotic effect (Sun et al., 2006); Sun and Bao demonstrated that herbal formula Yikang Decoction has a role in the treatment of male immune infertility caused by antisperm antibodies (Sun and Bao, 2006); and Qi et al. suggested

that the use of herbal formula (Qi et al., 2001). An in vitro study, including 7 herbal decoctions and 37 individual herbs, concluded that they possess antioxidant and anti-estrogenic activities (Tempest et al., 2008).

The only randomized study conducted with an herbal preparation was reported Park et al. in 2016. The authors randomized 77 infertile men with varicocele in 4 different groups: placebo, Korean red ginseng, varicocelectomy with placebo, or varicocelectomy with Korean red ginseng. They concluded that the patients treated with Korean red ginseng with or without varicocelectomy showed significantly improved semen parameters in terms of sperm concentration, viability, motility, and morphology. Although the effects were more prominent in patients who also underwent varicocelectomy, Korean red ginseng monotherapy also showed significant improvement in semen parameters (Park et al., 2016).

Tai Chi and Qigong

Tai chi and qigong are Chinese mind-body practices that combine meditation with exercise to improve the flow of qi throughout the body. The main difference lies in the complexity of movements, with qigong being a simpler form utilizing repetitive body movements and breathing techniques. Tai chi originated as a martial art that has evolved to an exercise promoted for general health. The role of both techniques in male infertility is to integrate body, breath, and mind, to achieve mental clarity, body homeostasis, and heightened sexual energy and libido, but there are no specific study addressing their efficacy in improving parameters of male fertility (Yao and Mills, 2016).

Ayurvedic Medicine

In India, indigenous use of plant products has been an ancient practice and plays an essential part of healthcare system. Information about herbal or plant-based therapies and their efficacy has been documented in the Vedas and the knowledge has been transferred from one generation to another (Lohiya et al., 2016).

Withania somnifera (Indian ginseng) is reported to have antiserotogenic, antioncogenic, cardioprotective, anticoagulant properties and its roots is considered as an aphrodisiac and a tonic (Lohiya et al., 2016). Ambiye et al. showed a marked improvement in semen parameters and testosterone levels after 90 days of treatment with *W. somnifera* root extract in oligospermic men (Ambiye et al., 2013).

Another plant, *Tribulus terrestris* has been implicated in the treatment of male infertility. In a double-blind study, Sellandi et al. observed that administration of *T. terrestris* granules improved sperm count in 78% of the oligospermic patients. The possible mechanism of action is attributed to its ability to increase the production of LH, which subsequently increase testosterone levels (Sellandi et al., 2012).

Yoga

Yoga is a physical, mental, and spiritual discipline that originated in India. Yoga focuses on gentle stretching, exercises for breath control, and meditation. The role of yoga in male infertility focuses on reducing anxiety and optimizing erectile function (Sengupta et al., 2013).

Homeopathy

Homeopathy is a system of alternative medicine created in 1796 by Samuel Hahnemann. Homeopathy rationale sustains that a substance that causes the symptoms of a disease in healthy people would cure similar symptoms in sick people. The preparations are manufactured using a process called homeopathic dilution, in which a substance is repeatedly diluted in alcohol or distilled water.

In a prospective observational pilot study, 45 patients were treated with homeopathic drugs for an average of 10 months. Those patients with low alcohol consumption, nonsmokers, with less than five dental amalgam fillings, and no exposure to noxious substances at the workplace showed better results. Overall, patients with oligoasthenospermia and severe oligoasthenoteratospermia showed median improvement by 184% in their sperm count and by 114% in their sperm progressive motility (Gerhard and Wallis, 2002). The authors also reported a pregnancy rate of 15.6% and live birth rate of 11.1% in patients in the treatment group who were infertile for at least two years (Gerhard and Wallis, 2002).

Medical Male Contraception

Morgan E Schubbe and Moshe Wald, University of Iowa, Iowa City, IA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Numerous methods for female contraception exist, including oral pills, implantable devices, transdermal patches, or intrauterine devices. However, many women are unable to use these methods due to intolerance or hormone-related side effects, leaving couples with limited options for safe and effective contraception. One area that has long been under investigation but is not yet available to the public is male medical contraception.

Male contraception can be broadly divided into three categories. First are methods that include physical barriers, such as condoms or vasectomy. Several other methods (both hormonal and nonhormonal) work by preventing the production of sperm. Lastly, there are agents that work by inhibiting sperm function or directly killing sperm.

Most contraceptive use among modern couples uses methods that place the burden solely on women. Currently, the only readily available methods of contraception for men include vasectomy and condoms. In 2015, male-directed methods accounted for 21% of contraceptive practice worldwide (United Nations, 2015). Since the latter part of the 20th century, the market has seen additions of new methods for use by women, including intrauterine devices. However, innovations in male methods have been limited to refinements in male condoms and improved vasectomy techniques. Many new methods of male contraception are currently in clinical trials, but not yet available in the United States.

This article will provide an overview of the methods of male contraception currently available commercially as well as those that are still experimental, as well as promising options that may be available in the future.

Currently Available Methods

Physical Barrier Methods

Condoms

Condoms remain the least expensive and most commonly used form of male contraception. They are relatively low cost, easy to use, have few to no side effects, and are the only method to also offer protection against sexually transmitted infections. According to the most recent National Survey of Family Growth (2006–10) male condoms had a failure rate of 13% within 1 year, down from 17% from the previous report in 2002 (Sundaram et al., 2017). This relatively high failure rate as well as perceived loss of pleasure are some of the main reasons men may not use condoms.

Vasectomy

Vasectomy is currently the most widely practiced surgical procedure for male contraception. Although it is safer, simpler, less expensive, and equally as effective as female sterilization, there is still a large discrepancy between female and male sterilization in many countries worldwide. The 2015 United Nations Population Division reported that male sterilization accounted for 10% or less of all sterilizations among couples (United Nations).

Vasectomy is a highly effective procedure with failure rates typically <1% (Sharlip et al., 2012). Failure is often due to lack of backup contraceptive use until azoospermia is confirmed or more rarely, late recanalization of the vas deferens. Most vasectomies are performed as outpatient procedures under local anesthesia with rapid recovery. The most common side effects include a 1%–2% risk of symptomatic hematoma and 3.4% incidence of infection. Additionally, 1 in 1000 men who undergo vasectomy will have long term pain requiring eventual medical or surgical intervention (Adams and Wald, 2009). Vasectomy is technically reversible, but is intended to be a permanent form of contraception.

Hormonal Methods

Methods of male hormonal contraception are the most widely studied, but remain unavailable for commercial use. Hormonal methods of contraception exert their effect by influencing a series of feedback loops on the hypothalamic-pituitary-gonadal (HPG) axis (Fig. 1).

The hypothalamus releases a hormone called gonadotropin-releasing hormone (GnRH) in a pulsatile manner. GnRH then travels through a local venous circulation to the anterior pituitary gland, where it stimulates the release of two important reproductive hormones called luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH are the primary pituitary hormones that regulate ovarian and testicular function.

In the testis, LH stimulates testosterone production within the Leydig cells. FSH binds to Sertoli cells and spermatogonial membranes and stimulates seminiferous tubule growth. When a male reaches puberty, secretion of LH and FSH from the anterior pituitary increases. The seminiferous tubules become the site of sperm production. This process is initiated when circulating testosterone and other local factors bind to the immature germ cells to induce their maturation.

Fig. 1 Schematic representation of the hypothalamic-pituitary-gonadal (HPG) axes. From Kong L., et al. 2014. *International Journal of Molecular Sciences* **21**,253–269; MDPO Open Access.

The effects of exogenous testosterone on this axis work via a negative feedback loop to inhibit LH and FSH secretion from the pituitary gland. Decreased levels of LH and FSH in the testes lead to decreased production of endogenous testosterone, which is required for spermatogenesis. This effect can be augmented by the addition of progesterone analogues or GnRH antagonists, which will be discussed later in this article.

Overview of spermatogenesis

Spermatogenesis is a complex, hormonally regulated process. In humans, spermatogenesis begins in puberty and continues for life. The process is started when the hypothalamus secretes a substance called GnRH, which stimulates downstream release of FSH and LH that ultimately reach the Sertoli cells and germ cells in the testes.

The majority of testicular volume is made up of structures called seminiferous tubules. Sertoli cells can be found lining the seminiferous tubules. These cells are responsible for providing structural, functional, and metabolic support to the developing germ cells (sperm). The inside of the tubules is highly organized, with the developing germ cells following a sequential order of maturation as they progress toward the seminiferous tubule lumen where they are released. The spermatogonia is an early form of the germ cell, and as it grows and divides it progresses through a series of stages including primary spermatocyte, secondary spermatocyte, spermatids, and finally, mature spermatozoa.

The entire process of sperm production takes approximately 60–75 days. It takes an additional 10–14 days for the sperm to be transported through the reproductive tract from the seminiferous tubules, until they eventually reach the ejaculate. The concentration of sperm in normal ejaculate typically ranges from 15 to 150 million sperm per milliliter of ejaculate. The complete absence of sperm, called azoospermia, makes fertilization impossible and thus is the ultimate goal of male contraceptives. Another term, oligospermia, refers to sperm counts < 15 million per milliliter. The more severe the oligospermia (i.e., the lower the sperm count), the lower the chances of successful conception. Some investigational methods of male medical contraception have demonstrated varying levels of oligospermia. Few methods aside from surgical vasectomy actually achieve full azoospermia, so counts < 1 million sperm per milliliter are considered by some a reasonable and successful target for male contraceptives (Aaltonen et al., 2007).

Hormonal preparations are available in multiple formulations, including injectable, implantable, transdermal, and oral. Oral preparations of testosterone are prone to high first-pass metabolism, a phenomenon in which the concentration of the drug is greatly reduced by the time it reaches systemic circulation. This necessitates two to three time per day dosing and makes oral testosterone a less practical option. One of the most highly studied formulations is high-dose testosterone depot injections. Two large, multinational, multicenter studies sponsored by the World Health Organization published in the 1990s showed that once-weekly 200 mg intramuscular injections of testosterone enanthate (TE) produced azoospermia in 65% of men after 4 months with 0–0.8 pregnancies per 100 person-years and oligospermia (defined as < 3 million sperm/mL) in all but 2.2% with associated pregnancy rates of 8.1 per 100 person-years (World Health Organization, 1990, 1996). The combined failure rate of this regimen was 1.4 pregnancies per 100 person-years, comparable with the female contraceptive pill. The regimen was largely well tolerated with common reversible side effects including weight gain, acne, increased aggressiveness and libido, hypertension, depression, fatigue, decrease in

testicular volume, and decrease in HDL. The failure in 2% of patients to achieve sufficient oligospermia and the inconvenience of weekly injections were considered the major disadvantages.

The addition of progesterone derivatives to testosterone increases inhibition of spermatogenesis by further inhibiting the pituitary gland and has potential direct effect on germ cells. The synergistic effect of these two substances allows for lower total use of testosterone to achieve sufficient azoospermia in a shorter time period than testosterone alone. In one study, oral levonorgestrel, LNG (500 µm orally daily) was combined with TE (100 mg IM per week) for 6 months. The LNG-TE combination was superior to TE alone in terms of azoospermia (67% vs. 33%, respectively) and 94% of the men had sperm concentrations of < 1 million per milliliter compared with 61% of the TE-alone group (Bebb et al., 1996). Drawbacks to the LNG-TE regimen included greater weight gain and decreases in HDL cholesterol compared with the TE alone group.

Side effects of progestones include weight gain, lower HDL, lower sex-hormone binding globulin levels, and promotion of proinflammatory cytokines that have been linked to adverse cardiovascular events (Zitzmann et al., 2005).

Similar to progesterone derivatives, GnRH antagonists work synergistically with testosterone to inhibit spermatogenesis. These substances work by competitive inhibition at the GnRH receptor in the pituitary gland, inhibiting the production and release of FSH and LH necessary to produce testosterone. Though promising in theory, studies so far have been small and have not shown significant difference in efficacy over testosterone alone. Downsides of GnRH antagonists appear to be local skin reactions and high cost.

An interesting observation with hormonal methods is their varying efficacy based on ethnic background. In numerous studies, increased effectiveness of hormonal contraception has been seen in East-Asian populations with azoospermia rates approaching 90%–100%. Men in Europe, North America, and Australia have rates of azoospermia between 60% and 80% on the same regimen (World Health Organization, 1990, 1996). The reason for this difference has yet to be discovered, but may be due to differences in body fat distribution or genetic differences in hormone metabolism.

Nonhormonal Methods

The promise of nonhormonal methods of male contraception is becoming more appealing because they have no impact on testosterone and thereby may avoid side effects such as sexual dysfunction or weight gain. These nonhormonal alternatives may also be more easily dosed orally as they do not have the first pass metabolism of testosterone. These compounds work in a variety of ways at the cellular level including influencing gene expression, receptor inhibition, and physical disruption of essential cellular connections. Four of the most researched nonhormonal substances are reviewed here.

Adjudin is a recently discovered compound that acts by disrupting adhesion between spermatids and Sertoli cells, causing premature release of sperm and resulting in infertility. This is a locally acting agent with no apparent toxicity to Sertoli cells. Because it does not work on the HPG axis, FSH and LH levels are preserved and future fertility is maintained. Adjudin is currently being studied in animals and has shown promising results in rats. Potential effects on the liver and costs associated with modifying the compound are obstacles for testing in humans.

Another compound that inhibits spermatogenesis is WIN 18,446, a potent inhibitor of testicular retinoic acid, which is essential to spermatogenesis. In seminiferous tubules, both germ and Sertoli cells synthesize retinoic acid via enzymes called aldehyde dehydrogenases. The retinoic acid then binds to receptors (RARs) that regulate gene expression. Male mice with abnormal retinoic acid receptors (RAR) are sterile due to problems with spermatogenesis (Kastner et al., 1996). Benefits of WIN 18,446 include reversible inhibition that suppresses spermatogenesis while preserving normal testosterone levels with a relatively benign side effect profile.

Another option for more selective inhibition is BMS-189453, an oral agent that selectively inhibits nuclear RAR. Unlike WIN 18,446 which takes up to 16 weeks to produce azoospermia, BMS-189453 has onset of action within 1 month and shows effects lasting up to 4 months (Chung et al., 2011). Rat studies have demonstrated this compound to be safe and effective for inhibiting spermatogenesis at low doses with no discernable side effects.

One final testis-specific target is an inhibitor of the protein BRDT. This protein functions to reorganize hyperacetylated histones, interfering with DNA synthesis. DNA synthesis is crucial to the production and differentiation of spermatocytes, so inhibiting this process will prevent formation of sperm. Male mice with selective inhibition of BRDT have been found to have isolated infertility (Shang et al., 2007). These effects are reversible upon withdrawal of the medication and there have been no significant systemic or hormonal side effects reported.

New Technology on the Horizon

One of the most promising developments in male contraception is an injectable technique that has been under investigation since the 1970s. Termed RISUG (reversible inhibition of sperm under guidance), it involves injection of a synthetic substance directly into the vas deferens under direct visualization through a small scrotal incision. The result is formation of a porous polymer that disrupts sperm-cell membranes as they move through the vas, producing damaged, nonviable sperm.

This technique has been extensively studied in India with promising results. Men achieved azoospermia within 1–4 months, with no pregnancies reported over 6 months (Chaki et al., 2003). Successful reversibility has also been demonstrated in several animal studies.

RISUG is currently under preclinical investigation in the United States under the trademark name Vasalgel (Parsemus Foundation, Berkeley, CA). Vasalgel is an SMA acid polymer dissolved in DMSO that works by occluding the vas deferens. After injection, the SMA acid forms a hydrogel that adheres to the tissues and fills the vas lumen, acting as a mechanical barrier to the passage of

sperm. In a study of adult rabbits, the injection produced reliable, durable azoospermia for study duration of 12 months; the substance was then flushed with successful restoration of fertility (Waller et al., 2016). The contraceptive effects of Vasalgel were reversible either with bicarbonate injection or digital massage.

Although promising, this method is still in need of broader multicenter clinical trials in humans to ascertain true safety and efficacy. The main safety concern surrounding this method includes potential teratogenic effects on sperm.

Summary

Despite years of research into medical alternatives for male contraception, the only commercially available options remain condoms and vasectomy. An ideal contraceptive is low cost, easy to use, reversible, and with few to no side effects. Although many of the hormonal methods have shown promising efficacy, they can require frequent dosing and have a wide range of side effects that many men are unable to tolerate.

Some of the nonhormonal compounds currently under investigation appear to have high efficacy. They target more specific steps in spermatogenesis and have shown relatively few side effects in many animal studies. More studies are needed to fully evaluate the safety and efficacy of these specific inhibitors in humans.

Perhaps one of the most promising new technologies is RISUG. Though similar methods have been under investigation in India for many years, this technology is just starting to gain interest in the United States and is currently in preclinical investigations. A local injection has the benefit of limited to no systemic side effects and has proven methods of reversibility. It is performed as a one-time outpatient procedure that is likely to be well tolerated and potentially cost-effective.

At the present time, medical options for contraception remain those available to women. Many women are unable to shoulder this burden due to cost, accessibility, or inability to tolerate hormonal side effects. Additionally, studies have shown that many men do take an interest in contraceptive responsibility. It is important to keep supporting investigation of these male contraceptive alternatives.

Introduction

Penile erection is the end result of a culmination of physiologic events which allows for satisfactory sexual activity. With initial stimulation, sensory efferents trigger the release of nitric oxide (NO) from the nerve terminal with resultant arterial dilation and inflow of blood into the penis. This causes the smooth muscle of the penis to relax. As the spaces of the penis (corpus cavernosum) fill with arterial blood and an erection is achieved, veins exiting the corpora cavernosa are compressed, further preventing the egress of blood so that the erection is maintained. Detumescence occurs as sympathetic stimulation causes contraction of the smooth muscle and returns to baseline after sympathetic triggered ejaculation.

Multiple vascular, neurologic, and psychologic pathways are involved in the steps required for a satisfactory erection. Impeding factors cause many men to struggle with achieving and/or maintaining erections, also known as erectile dysfunction (ED), with more than half of men over age 40 reporting some degree of ED (Feldman et al., 1994). After a directed history and physical examination with specific attention to medications, initial treatment typically consists of sexual counseling (if indicated) and a trial of oral medications with a phosphodiesterase inhibitor. If these options do not result in adequate improvements in erections or cause unwanted side effects, second-line treatments involving medications or devices directed locally to the penis are employed. In individuals with recalcitrant ED failing other therapies, surgical treatment with penile prosthesis implantation is recommended.

This article focuses on direct application therapy for ED, or non-surgical treatment with a delivery mechanism that requires direct physical contact with the penis. As mentioned, direct application therapies are often used as second-line therapy choices although some modalities may be utilized in first-line treatment. Currently available options include vacuum-assisted erection devices, penile tension rings, intraurethral vasodilatory suppositories, intracavernosal vasoactive injections, topical medications, and low-intensity shockwave treatment. Each treatment will be reviewed with emphasis on indications, general clinical use, mechanisms of action, results, and complications of therapy.

Direct Application Therapies for ED

Vacuum Erection Device

The concept for vacuum-assisted erections was first described by John King, an American family physician, in 1874 (King, 1874). The patient with “impotency, with a diminution in the size of the male organ” was instructed to bath the genitals with a shampoo of rosemary, phosphorus, tincture of musk, and almond oil followed by application of a “glass exhauster.” In 1917, the Austrian physician Otto Lederer took the design one step further, creating a combination device which employed a constricting ring at the base of the penis to maintain the erection. After his own radical prostatectomy, Geddings Osbon Sr. invented the modern vacuum erection device (VED) that was ultimately approved by the Food & Drug Administration in 1982. Thereafter VEDs gained popularity and were the most commonly prescribed therapy for ED until the emergence of phosphodiesterase inhibitors (Oakley and Moore, 1998).

A VED functions by creating a negative pressure environment around the penis to draw venous blood into the cavernous spaces (Fig. 1). Before using the device, a well-lubricated penile constriction ring is loaded onto the base of the plastic or glass cylinder. The cylinder is subsequently placed over the penis and a manual or battery-operated pump is activated to create a vacuum until the penis is engorged. Once the desired erection is achieved, the constriction band is slipped off the cylinder at the base of the penile shaft to prevent venous outflow and maintain rigidity for sexual activity. VEDs are indicated as first- or second-line therapies for ED and can

Fig. 1 Schematic of vacuum erection device. Image courtesy of OneMed Solutions.

be used as monotherapy or in combination with oral medications. In addition, a VED has been utilized in men with conditions contributing to corporal fibrosis or scarring (e.g., following radical prostatectomy or a prolonged episode of priapism) and may have a role in treating penile curvature as a result of Peyronie's disease.

VEDs have proven benefit for men with ED but efficacy is strongly dependent on proper usage of the device. Dedicated training sessions for patients learning to use a VED should be considered. With proper usage, up to 90% of men report satisfactory erections for penetrative intercourse (Montague, 2002). Continued usage at 2 years for those initially choosing a VED is up to 69%. Despite high initial success rates however, 86% of men will move on to other treatment choices for their ED when given additional options (Baniel et al., 2001).

Continued use of VEDs tends to be poor as many men struggle to integrate the cumbersome mechanical aspects of the device with their sex life. Some will discontinue the device secondary to quickly waning erections during intercourse, often the result of an inadequate seal of the constriction ring at the base of the penis. The seal of the ring may be improved by trimming pubic hair or using a lubricating jelly. Men with short or buried penises may be physically unable to achieve an adequate fit of the cylinder around the phallus secondary to anatomical challenges. It is also important to consider the natural anatomy of the penile corpora cavernosa which start in the glans penis, extend through the shaft, and insert under the pelvic rami. The constriction ring is placed at the base of the penis and holds blood in the penile section of corpora only, resulting in erectile instability or "hinging" as the proximal proximal corpora remain flaccid. Men also note an unnatural feel and appearance (cool and bluish) of the erection related to the retrograde venous inflow of blood in contrast to physiologic erections which contain arterial blood. Complications tend to be rare but may include petechiae and ecchymoses from VED usage. Concomitant usage of a VED in men on active anticoagulation is relatively contraindicated due to the theoretical increased risk of bruising and hematoma.

Penile Tension Rings

Constriction or tension rings were originally developed as a component of VEDs to aid in maintaining erections. The rings function in augmenting venous constriction to retain blood in the corpora for penile rigidity. Ideally, a penile tension system would be tight enough to constrict draining veins but still allow some arterial inflow into the corpora to achieve a maximally rigid erection. As such, constriction rings may also be utilized in men with innate venous dysfunction typically heralded by a complaint of strong rigid erections (either natural or with oral medications or penile injections) that quickly wane during intercourse.

Rings are available in a variety of sizes, shapes, and materials that together impart varying levels of penile constriction. Additionally, rings have varying designs to allow easier application and removal, a useful feature for men with limited dexterity. When purchasing a penile tension rings (and not a complete VED), it is important for men to purchase an appropriate application system that includes a loading cone and penile bushing/cylinder to allow for easy deployment.

Little research has focused on the success or satisfaction with penile tension rings alone or in conjunction with oral/injectable erectile medications. The major limiting factor for men using constriction rings is, again, cumbersome application of a mechanical device during sexual activity. Some men may experience mild discomfort with the ring in place or sensitivity to the material. If the ring is causing significant pain, it is likely not sized appropriately. Men may also complain that ejaculation is obstructed or limited with the ring in place. Blood gas analyses have demonstrated that penile ischemia begins approximately 30 min after applying the constriction ring, therefore it is not recommended to leave the device in place longer due to risk of necrosis and gangrene (Yuan et al., 2010). Metal rings should be avoided because they can require complex removal when associated with penile edema or swelling.

Urethral Suppositories

In an effort to avoid more invasive medication delivery to the penis, namely injections, intra-urethral suppositories were developed to deliver a vasoactive agent locally to the penis. As described later, alprostadil (a synthetic form of prostaglandin E1) was initially utilized as an injectable treatment for men with ED. Alprostadil acts by directly increasing cAMP levels, leading to arterial vasodilation and penile erection. The medication was placed in a dissolvable urethral suppository to work locally at the level of the penis without requiring a needle. MUSE® (Medicated Urethral System for Erections) was introduced as the first and only FDA approved alprostadil urethral suppository medication in 1996, 2 years before sildenafil would be approved.

The patient is required to initially urinate before using the urethral suppository to lubricate the urethra. The suppository comes in an applicator (Fig. 2) that is gently placed into the urethra and the deployment button pushed to release the suppository (Fig. 3). After removing the applicator, the penis should be rolled firmly for 10 s to assist in proper setting, dissolution, and distribution of the medication equally along the urethral epithelium. Pharmacologically, the medication acts through local diffusion of prostaglandin into the corporal tissues to initiate arteriolar vasodilation and penile erection. Erection typically occurs within 5–20 min after deployment. MUSE® is available in 125, 250, 500, and 1000 mcg dosages.

Urethral suppositories, like VEDs, are typically utilized as a second-line treatment choice for ED but can be used as a first-line treatment in select individuals (e.g., those with contraindications to phosphodiesterase inhibitors). After initial dose titration, 40%–65% of men with ED reported adequate erections for intercourse at home (Costabile et al., 1998; Padma-Nathan et al., 1997). Studies demonstrated success in men with ED secondary to various organic causes, though the series reporting up to 65% success excluded poorly controlled diabetics and spinal cord injury patients. Long-term urethral suppository compliance is poor with upwards of 30% of users discontinuing treatment within the first year (Nandipati et al., 2006).

Fig. 3 Method of placement of intraurethral suppository. Image courtesy of Mylan Pharmaceuticals Inc.

Side effects from the use of urethral suppositories tend to be minimal. Men often experience mild discomfort with initial medication deployment with 5% reporting urethral trauma (Padma-Nathan et al., 1997). Nearly one third of men have penile pain or burning with intra-urethral alprostadil that is more pronounced at higher dosages. Rarely men may report dizziness thought to be secondary to the vasodilatory properties of the medication although no patients experienced clinical hypotension in the cited study. While less cumbersome than a VED, some men may find the suppository off-putting in its disruption to the natural flow of a romantic encounter. The same could be said of penile injections, however urethral suppositories do require extra effort to dissolve and distribute the medication. They are very expensive as well.

Intracavernosal Injections

Intracavernosal injection (ICI) therapy refers to direct injection of a vasodilatory medication or combination of medications into the corpus cavernosum to induce an involuntary erection. The technique was discovered in 1977 when papaverine was inadvertently injected into the cavernosum during a surgical shunting procedure and induced a rigid erection in a patient with known ED (Michael et al., 1997). After further pharmaceutical research, alprostadil for ICI was FDA-approved in 1995 and became the first prescription medication available for men with ED. ICI remains an attractive and highly successful option today for men desiring natural appearing erections with suboptimal efficacy or poor tolerance of oral phosphodiesterase inhibitors.

While original ICI studies reported the use of papaverine, the first FDA approved agent was alprostadil. Since then, there has been an introduction of other agents, namely phentolamine and atropine, to the injectable armamentarium. Alprostadil remains the most commonly used *single-agent* injectable under the trade names Edex® and Caverject®. After injection, alprostadil triggers direct corporal artery vasodilation by increasing cAMP levels. Papaverine is a nonspecific phosphodiesterase inhibitor which similarly increases intracellular levels of cAMP and cGMP. Phentolamine is an alpha-1 adrenergic antagonist that opposes sympathetic-mediated vasoconstriction of cavernosal arterial inflow, effectively keeping the arteries open.

Alprostadil injection alone may be insufficient for some men with vascular etiologies of ED and, thus, combinations of the vasoactive agents above have been developed. While combination therapy is not FDA approved, many physicians prescribe ICI mixtures to compounding pharmacies for treatment of ED. The combinations are referred to as Bimix (papaverine and phentolamine), Trimix (alprostadil, papaverine, and phentolamine), and Quadmix (alprostadil, papaverine, phentolamine, and atropine) based on the number of components of each. The combination and concentration is selected by the prescribing physician based on the

Fig. 4 Left: Schematic of intracavernosal injection of vasoactive agent. Right: Cross-sectional anatomy of injection placement. Image courtesy of OneMed Solutions.

severity of the patient's ED and medication side effect profile. Bimix, for example, does not include alprostadil which can cause burning penile discomfort in some men. While no standard dosing exists for these medications, they are typically implemented at low doses and titrated based on patient response.

Injectables are available in pre-filled auto-dosing syringes or standard medication vials. Patients should be instructed in proper medication preparation and cleaning of the skin with alcohol before injection. Only the amount prescribed should be injected, unless directed otherwise. The injection should be performed on the lateral aspect of the penile shaft, taking care to avoid visible veins and stay away from the glans and ventral (bottom side) penis where the urethra is and the dorsally (top side) where the blood vessels and nerves travel (Fig. 4). Temporary pressure should be held on the injection site with erection typically occurring within 5–15 min.

ICI is an ideal second-line treatment choice for men that have not achieved adequate results with other first-line treatment options (oral medications, VED, or urethral suppository) or is unable to tolerate associated side effects. Injections are very efficacious with approximately 85% of users achieving adequate erections after dose titration (Hanash, 1997). Despite high success rates, the discomfort with penile injection and other side effects lead many men to stop ICI therapy with data showing 40% stopping injections in the first year alone (Mulhall et al., 1999).

Side effects of penile pain, bleeding, and bruising are common but tend to be mild and well tolerated. Additional possible complications include penile burning, scar tissue, or penile curvature. Injection sites should be rotated in an effort to avoid scar formation. Priapism, or an erection lasting longer than 4 h, can occur if too much medication is injected and represents a *medical emergency*. When an erection remains rigid over an extended period of time, there is a lack of oxygenated blood flow and the corpora become increasingly ischemic with risk of worsening future ED. Initial testing and dose titration in the office is highly recommended to ensure a safe and effective transition to home ICI therapy.

Topical Therapies

Topical therapies for ED include various creams and gels that are applied to the penile skin or urethral meatus to induce an erection. Available products are composed of the familiar vasoactive agents discussed earlier. Vitaros[®] contains a prostaglandin E1 cream for perimeatal application and is commercially available throughout Europe for treatment of ED. There are no FDA approved topical treatments in the United States as of the writing of this article though some compounding pharmacies offer a gel formulation of Trimix. When the patient wishes to use the product (Vitaros[®], Trimix, or other), the product is gently applied with an applicator or finger to the penile skin (typically the glans) or meatus as directed. The glans is massaged with meatal application to promote absorption. Penile erection should occur within 5–30 min of application.

The theory behind topical creams/gels is that the vasoactive agents will be able to diffuse across the penile or urethral epithelium and enter the corpora cavernosum where they can induce erection. Active medications may be coupled to a fatty acid or ester meant to promote local diffusion through the urethral epithelium. Topical agents were developed in an effort to utilize local vasoactive medications while avoiding the discomfort and inconvenience of an injection or urethral suppository.

Several randomized controlled trials have demonstrated that topical therapies may serve a role in the treatment of ED (Hellstrom and Anaissie, 2016). Results are generally modest but men report a significant improvement in the ability to achieve intercourse with both subjective and objective increases in erectile function. A small percentage of men may experience local irritation with redness or pain at the site of application, and, rarely, the patient's partner may report similar symptoms secondary to transference during intercourse. Though exceedingly rare, symptomatic hypotension has been reported. This treatment is not utilized very often in general practice.

Low-Intensity Extracorporeal Shock Wave Therapy (LI-ESWT)

Extracorporeal shockwave therapy, known in urology for years for its ability to fracture stones, has shown some application in the form of low-intensity extracorporeal shockwave therapy (LI-ESWT) in the fields of orthopedics, trauma, and cardiac disease. It exerts

its effects via stimulation of vascular endothelial growth factor upregulation of the NO cascade, promoting angiogenesis. Treatment utilizes a focused electrohydraulic, electromagnetic, or linear piezoelectric shockwave lithotripter to apply 600–3000 low-intensity shocks along the shaft and crura of the penis. While treatment protocols have varied between series, patients have generally received individual treatments several times per week over a course of a few weeks.

Eight randomized controlled trials have evaluated the efficacy of LI-ESWT on improvements in erectile quality using validated questionnaires and scales of erectile hardness. A meta-analysis of available studies demonstrated a modest but significant improvement in erectile quality scores while the most recently published double-blinded, sham-controlled trial showed no benefit (Clavijo et al., 2017; Fojecki et al., 2017). As of yet, the efficacy of LI-ESWT has not been established and therefore is not widely offered unless under a research protocol. Due to possible angiogenic benefits, some LI-ESWT trials have specifically targeted phosphodiesterase inhibitor non-responders and post-prostatectomy ED with further research needed.

Side effects are rare with those reported including mild penile pain, irritation, and ecchymosis. The most efficacious treatment schedule still needs to be determined but will likely involve numerous treatments spaced out over several weeks. Many men may find the time required for therapy to be onerous and perhaps prohibitive for such a marginal benefit. The durability of any response to treatment is largely unknown. Future trials in LI-ESWT are still required to determine optimal shockwave strength, depth of penetration, and delivery schedule, and ultimately whether or not it has a place in the treatment algorithm for ED.

Summary

Many men move on from oral medications due to inadequate results or unwanted side effects such as headaches, flushing, or sinus congestion. In such cases, direct application therapies including VEDs, penile tension rings, urethral suppositories, ICI, or other investigational treatments are typically recommended. VEDs and penile tension rings represent mechanical options while urethral suppositories and ICI target vasodilatory medications to the corpora cavernosum. Each choice has proven efficacy with the highest success rates and most natural erections reported with ICI. Men should be encouraged to have an open dialogue with their physician about ED symptoms and how direct application therapies may improve their sexual quality of life while minimizing side effects. Treatment with topical agents (outside Europe) and LI-ESWT is still investigational but may offer an additional therapeutic strategy in the future.

Medical Therapy of Peyronie's Disease

Alexandra J Berger and Martin N Kathrins, Harvard University, Cambridge, MA, USA

© 2018 Elsevier Inc. All rights reserved.

Introduction

Oral and intralesional medical therapies have been studied extensively in the treatment of Peyronie's Disease (PD). While there are no FDA approved oral therapies, pentoxifylline, colchicine, potassium aminobenzoate and co-enzyme Q10 all have some level of supportive evidence. Intralesional injections including collagenase clostridium histolytica (CCH), interferon α -2b, and to a lesser degree verapamil have also been investigated and found to have different levels of documented benefit. Mechanical traction has limited efficacy as an adjunct to these therapies.

PD begins with repeated microvascular trauma to the penile shaft caused by penile buckling in the erect or semi-erect state; this most often occurs during sexual activity. This trauma is typically minor and in many cases patients cannot recall any specific event. Following this repeated trauma, a cascade is initiated where there is significant extravascular protein deposition, fibrin trapping, macrophage recruitment and release of elastase. After a period of time, there is significant local scarring which leads to plaque formation and curvature of the penis.

The natural history of PD is variable; in many patients symptoms may resolve on their own with data suggesting about 90% of patients have improvement in pain one year after symptom onset. In about 50% of men, penile curvature either stabilizes or resolves at one year with the remainder of patients experiencing curvature worsening after the subacute period.

Oral Medications

Oral therapies used to treat PD are intended to reverse or reduce the underlying inflammatory pathophysiology of the condition. There is limited evidence to support the use of any of the currently existing oral medications which have been studied. The 2015 American Urological Association guidelines on Peyronie's disease listed pentoxifylline, colchicines, potassium aminobenzoate and co-enzyme Q10 as "possibly promising without sufficient evidence."

Pentoxifylline is a xanthine derivative nonselective phosphodiesterase inhibitor which is used to treat muscle pain in people with peripheral arterial disease. It has also been used off label to reduce fibrosis in a variety of conditions. Two recent studies—one randomized and one observational—demonstrated efficacy in the management of PD. However, data remains limited.

Colchicine is another anti-inflammatory medication that has been applied to the management of PD. Traditionally used to treat gout, the medication inhibits microtubular polymerization and therefore mitosis, and reduces neutrophil mobility and activity which leads to a net anti-inflammatory effect. While there is some data to support its use in the management of PD, a randomized placebo controlled study has not yet been performed.

Potassium aminobenzoate (Potaba) has been used since the late 1950s in the management of PD and has been deemed by the FDA as "possibly effective" in the treatment of the condition. The exact mechanism of the anti-fibrotic effects of this agent are as yet unknown, but they are believed to increase MAO-mediated serotonin degradation. While there have been two studies demonstrating its efficacy, its use is significantly limited by a poor side effect profile which includes nausea, anorexia, photosensitivity, anxiety, and difficulty concentrating.

Co-enzyme Q10 is a vitamin-like, anti-oxidant substance found in all aerobic eukaryotic cells and is a component of the electron transport chain participating in cellular respiration. The fully reduced form of Co-enzyme Q10 (ubiquinol) is also known to inhibit oxidative damage to polyunsaturated fatty acids and therefore exert an anti-inflammatory effect. Co-enzyme Q10 has been shown in one randomized control trial to reduce curvature and plaque size in patients with PD. However, there was no improvement in pain in these patients (Safarinejad, 2010).

Vitamin E, tamoxifen, procarbazine, omega 3 fatty acids and L-carnitine have all been investigated and found to be ineffective for the management of PD. Vitamin E (tocopherol) is an antioxidant which acts by scavenging oxygen free radicals; it was hypothesized that these antioxidant effects reduce fibrosis. While it is inexpensive, safe and has been used for this indication since the 1940s, recent literature does not support its use. Tamoxifen, a nonsteroidal antiestrogen, showed promise in one early 1990s study of PD. However subsequent placebo controlled reports on the medication have yet to demonstrate efficacy even when used in combination with other agents. Procarbazine is an alkylating chemotherapeutic agent used to manage CNS lymphoma, Hodgkin's lymphoma and high-grade gliomas. It was noted to have anti-fibrotic effects when used in Dupuytren's contracture and given the pathophysiologic similarities between this disorder and PD, it was subsequently studied for the latter condition. Unfortunately none of these studies demonstrated any efficacy and the extremely poor side effect profile of myelosuppression, hepatotoxicity, fatigue and GI distress limited additional investigation. Omega-3 fatty acids have known anti-inflammatory effects and are very well-tolerated but have been shown in multiple investigations, including a randomized placebo controlled trial, to have no benefit in patients with PD. L-Carnitine is an acetyl coenzyme A inhibitor which decreases free radical formation and therefore inflammation during times of stress. While it initially showed promise in reducing penile curvature, more robust trials did not demonstrate improvement with this medication.

Intralesional Therapy

Injection of intralesional therapies, including collagenase, interferon α -2b, and verapamil, is the mainstay of medical treatment for PD. Currently, only collagenase is FDA approved for PD, however all three medications have been shown to be both effective and relatively well tolerated.

Intralesional Collagenase *Clostridium Histolytica*

Intralesional collagenase *clostridium histolytica* (CCH) is currently marketed under the trade name Xiaflex. It was FDA approved for the treatment of PD in December 2013 for patients with palpable plaques and stable penile curvature greater than or equal to 30° at the start of therapy. CCH is an enzyme produced by the bacterium *clostridium histolytica* which breaks down collagen. It consists of a mixture of two collagenases, AUX-I and AUX-II. These act synergistically to cleave tropocollagen at different locations. CCH injections are considered extremely safe from a systemic standpoint because the enzymes do not enter the bloodstream. Instead, it is presumed that they stay at the point of injection where they are broken down by proteases. The medication is also approved for use in Dupuytren's contracture.

The earliest studies investigating CCH for PD began in the 1980s. The most robust data for CCH comes from two identical phase 3, randomized, double-blind, placebo-controlled studies—IMPRESS I & II—which demonstrated a 34% improvement in curvature when compared to placebo, who had only an 18.2% improvement. The average curvature reduction in existing literature is about 17°.

A single CCH treatment cycle consists of two injections which are given 48–72 h apart. A clinician must then perform modeling of the penis on a third office visit, and instruct the patient on how to do this himself at home. The modeling technique consists of two actions. First, there is a stretching activity performed when the penis is flaccid and a straightening exercise (gentle manual bending of the penis in the opposite direction of the curve) which is undergone when the penis is erect. The patient must perform daily modeling at home for approximately 6 weeks after they are instructed by their physician. Patients may receive a maximum of four cycles of CCH injections with approximately 6 weeks in between cycles. Patients are counseled not to have sexual intercourse in between the first and second injections of the treatment cycle and for 2 weeks after the second injection.

Patients most likely to benefit from CCH injections are those with stable disease, curvature between 30° and 90°, and with adequate erectile function either with or without the use of erectile aids. It is not as effective in men with calcified plaques. Furthermore, if the patient's predominant symptoms are pain or erectile dysfunction, CCH injections are unlikely to be of benefit.

The lack of systemic absorption of CCH injections makes this medication generally safe. The majority of patients experience penile ecchymosis but this is generally self-resolving. Other frequently reported mild or moderate adverse events include penile pain and penile swelling. Less than 1% of patients experience the more serious complications of penile hematoma requiring surgical intervention and corporal rupture. In studies, even these serious complications rarely required surgical intervention. In the IMPRESS trials, < 10% of treated patients either withdrew from treatment or were lost to follow-up.

Interferon α -2b

Interferon (INF) α -2b is an immunomodulator and cellular proliferation suppressor which is approved for management of hairy cell leukemia, follicular cell lymphoma, AIDS-related Kaposi sarcoma, malignant melanoma and chronic hepatitis B & C. Interferon α -2b reduces fibroblast proliferation and collagen synthesis, which have a natural application in PD considering its pathophysiology. It was first studied for use in PD in the mid-1990s and was shown in observational studies to stabilize or reduce plaque size in these patients. One subsequent randomized controlled trial demonstrated curvature improvement of around 13° (versus placebo improvement of 9°) as well as decreased plaque size, penile pain and penile hemodynamics. However, other randomized and observational studies have had mixed results with only some demonstrating benefit. Interferon has not been shown to improve erectile function. The current recommendation is that interferon α -2b injections are appropriate for patients with curvature > 30° without calcified plaques who have good erectile function (Nehra et al., 2015).

Interferon α -2b is injected intralesionally with frequencies ranging from once every 2 weeks to three times weekly. Treatment is typically for 12–24 weeks. Doses in the literature range from 1×10^6 to 5×10^6 units.

Unlike CCH injections, interferon α -2b has systemic effects. 40–100% of patients in the existing literature reported sinusitis and flu-like symptoms consisting of fever, chills and arthralgias. Typically, these effects are self-limiting and last < 48 h and can be managed with NSAIDs. Other adverse events, as with other intralesional therapies, include penile swelling and ecchymosis.

Verapamil

Verapamil is a calcium channel inhibitor and traditionally used to treat cardiac arrhythmias and angina. Calcium channel blockers are also known to alter the metabolism of fibroblasts, decrease collagen secretion and stimulate collagenase activity. Because of this, verapamil was proposed as a locally injectable agent for the management of PD. While the initial observational data on verapamil intralesional therapy was promising, the current evidence is weak. Multiple randomized controlled trials and observational studies have been performed with mixed results. While there is modest evidence to suggest verapamil improves penile pain and decreases curvature, many of the studies were performed on patients in the acute phase of PD when the clinical course is more uncertain and

variable. It is therefore difficult to extrapolate from this body of evidence to patients suffering from chronic PD. Current guidelines suggest verapamil can be considered in patients with more acute PD with the acknowledgement that the data to support its use is weak. Nicardipine is also under investigation, but is not currently recommended use in PD.

The dosing and frequency of verapamil administration varies widely in the literature. One typical regimen is a formulation of 10 mg of verapamil in 10 mL of normal saline injected into the Peyronie's plaque 6–12 times with 1–2 weeks in between each injection. It is suggested that the practitioner puncture the skin once, manipulating the needle in different directions to deliver the medication throughout the plaque. It is thought that the mechanical effect of manipulating the plaque with the injection needle is therapeutic in and of itself. Verapamil is considered very safe. Side effects consist primarily of penile hematoma and injection site discomfort. This is mostly due to the large volume of injection required. Systemic effects such as dizziness, nausea, loss of libido, weakness and sweating are rarely observed.

Other Intralesional Agents

There are limited studies on other intralesional agents for management of PD. However, none of these are widely used and they are largely investigational at this stage. Liposomal recombinant human superoxide dismutase (LrhSOD) has been found to be effective in very limited literature. Other medications under investigation include intralesional parathyroid hormone, steroids and iloprost. The existing data for these therapies is all observational and cannot be extrapolated to the population at large given small sample sizes and lack of control for natural history of the disease. There is also a body of literature on the use of intralesional agents in combination with oral agents, but this data is similarly varied and underpowered.

Mechanical Therapies

Penile traction therapy (PTT) has been investigated in multiple studies to treat PD either alone or in combination with oral or intralesional therapy. A penile traction device is composed of a plastic ring that fits around the glans of the penis and is attached to two movable rods that run down the sites of the penis. These rods apply tension longitudinally along the penile shaft, gently pulling and straightening over a period of months. Older data suggested modest improvement in penile length in patients who perform penile traction for 4.5–5 h per day. However, more recent studies have not found improved outcomes when traction is utilized in combination with CCH intralesional and other therapies. Nevertheless, these devices are commercially available for patient use and additional studies are ongoing.

Extracorporeal Shock Wave Therapy (ESWT)

Shockwave therapy has been studied in PD patients for many years. This treatment modality has been shown to be effective in management of orthopedic disorders such as epicondylopathies and given the pathophysiologic similarities between these conditions and PD it was hoped that ESWT would be similarly effective in patients with PD. While early data was promising, the bulk of the literature has not demonstrated efficacy of ESWT for PD. Many studies have failed to show improvement in curvature and plaque size. There is limited data to suggest ESWT may improve penile pain in patients with PD, but this may be an effect of the natural history of PD in that many patients initially have pain but this improves over time.

ESWT is associated with frequent adverse events which include localized petechial bleeding or bruising, urethral bleeding or transient hematuria and ecchymosis. A more severe risk is penile pain which has been reported in 2–4% of patients. Because of the poor side effect profile and lack of efficacy in reducing curvature and plaque size, ESWT is only recommended for well-selected patients to manage pain associated with PD.

Conclusion

Medical treatment modalities for PD include oral therapies, intralesional injections, penile traction therapy and ESWT. To date, intralesional CCH remains the mainstay of care for PD with only limited data to support the other therapeutic non-surgical options.

TREATMENT: SURGICAL

Overview: Surgical Treatment and Male Reproductive Medicine

Samuel Ohlander, University of Illinois-Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Over the last 20 years, diagnostic advancements allowing for improved patient selection and refinement of surgical technique have revolutionized male reproductive care. We now know that non-obstructive azoospermia does not preclude a man from fathering biologic offspring. Our improved understanding of genetics has allowed us to counsel our patients as to the possibility of successful retrieval versus those in whom operative measure would be futile. Furthermore, utilization of the operative microscope in surgical sperm extraction allows for targeted retrieval with visualization of gravid tubules.

On the other hand, 5% of azoospermic men have an obstructive etiology ([Fertil Practice Committee, 2008](#)). Up to 6% of vasectomized men will seek reversal ([Sandlow and Nagler, 2009](#)). Reconstruction, along with sperm retrieval, remains at the cornerstone of male reproductive care. Our better understanding of vasal fluid aids intraoperative decision making. We continue to seek diagnostic criteria to provide preoperative predictors of success, though, unfortunately, an ideal formula still evades us. Vasoepididymostomy technique has undergone refinement from fistula creation to single-tubule end to side anastomosis to triangulation to two-suture intussusception with patency rates reaching 70%–90% and lower shut-down rates, though surgeon experience remains a critical factor ([Chan et al., 2005](#); [Kolettis and Thomas, 1997](#); [Schiff et al., 2005](#)).

A number of chapters in this section will focus on the surgical management of subfertility. Topics will range from reconstruction to oncofertility. At the crux of all discussion it must be highlighted that as our abilities evolve, so must our counseling. Intracytoplasmic sperm injection (ICSI) has allowed for fertilization with a single sperm. Many of the obstacles associated with severe male factor infertility may now be bypassed, though our understanding of associated genetic consequences is incomplete. Furthermore, more men are surviving cancer, subsequently living longer and desiring families. Future reproductive potential is required in survivorship discussions.

Other chapters will discuss the surgical management of erectile pathology. While reproductive potential is not dependent on erectile function, it does play a significant role in natural conception and sexual satisfaction. Penile prosthetics have been an established treatment option for refractory erectile dysfunction for over 40 years. Modifications have been made over time, but the basic technology and surgical principals have been preserved. Patient and partner satisfaction rates following implantation are incredibly high, owing not only to our surgical abilities, but perhaps more importantly to our patient selection and counseling. The same preoperative measures must be emphasized for management of penile curvature. Advancements in medical therapy for Peyronie's Disease has led to less utilization of operative management, yet surgery continues to have a significant role. Patient understanding of the surgical goal of functionality is paramount.

Finally, further chapters will focus on the very sensitive subjects of sexual development and gender reassignment. This text is not meant to impose ethical beliefs, but simply discuss surgical considerations. Though mentioned throughout this overview, patient selection and appropriate preoperative counseling may be of greatest importance here. For all aspects of reproductive care, physicians must be sensitive to the struggles of the patient. Issues of self-worth and personal identity correlate strongly with reproductive health. Our clinical evaluation and surgical management must not merely focus on what we have the ability to do, but rather what offers our patients the greatest potential for improved function and quality of life while maintaining minimal risk.

Ultimately, reproductive physicians must continue to invest time and resources into science, to better understand the pathologies we treat and the implications of our clinical and technologic advancements.

Treatment: Surgical—Current Tools

Kevin A Ostrowski, University of Washington School of Medicine, Seattle, WA, United States

© 2018 Elsevier Inc. All rights reserved.

Surgical treatment of male infertility involves three main objectives: improving fertility, identification and procurement of testicular sperm or restoration of fertility through vasectomy reversal. Data on these treatments is mostly retrospective in nature and all treatments will be discussed and evaluated.

Surgical Techniques to Improve Fertility

Varicocelectomy

Varicocele's are found in 15% of men and increases to 40% of men seen for a fertility evaluation (Clarke, 1966). The indications for treatment of a palpable varicocele is testicular pain, abnormal semen parameters with desire for fertility, and testicular atrophy on the same side as the varicocele. Newer articles have evaluated treating larger varicoceles to improve testosterone however this is provider preference (Practice Committee of the American Society for Reproductive Medicine, Society for Male Reproduction and Urology, 2014).

There are three main surgical treatment options for varicocelectomy: laparoscopic, subinguinal and retroperitoneal. The nonsurgical treatment option is coil embolization normally done by interventional radiology. Laparoscopy has the risk of entering the abdominal cavity and retroperitoneal varicocelectomy has a higher recurrence rate with most surgeons using an inguinal or subinguinal approach with use of optical magnification and Doppler ultrasound (US) of the artery (Practice Committee of the American Society for Reproductive Medicine, Society for Male Reproduction and Urology, 2014). The subinguinal approach is done through a 2 cm incision in the inguinal area. The cord is identified and the external and internal spermatic fascia are opened. The testicular artery is identified with use of a Doppler ultrasound and the lymphatics, artery and vas are preserved. All major veins are either clipped or tied. The incision is closed.

Infertility improvements are theorized to be from optimization of testicular temperature for spermatogenesis and reduction in reactive oxygen species. Significant data has shown improvement in DNA fragmentation after varicocelectomy (Smit et al., 2010; Alhathal et al., 2016). In addition, there are improvements in fecundity with natural pregnancy, intra-uterine insemination (IUI), and in-vitro fertilization (IVF) after varicocelectomy on the recent meta-analysis (Kirby et al., 2016).

Finally, varicocele surgery in non-obstructive azoospermic (NOA) patients is controversial but in published studies there can be sperm seen in the ejaculate in up 40% of men after varicocelectomy (Weedin et al., 2010). Even if patient's remain azoospermic after varicocele repair, there are improved sperm extraction rates (Kirby et al., 2016). However, not all patients will improve after surgery and it will take up to 3 months minimum to see effects of surgery making the partner's fertility very important in this decision making.

Vasectomy Reversal

6% of men who undergo vasectomy will have a vasectomy reversal (Sandlow and Nagler, 2009). At the time of vasectomy reversal fluid is evaluated from the testicular vas and the decision is made for vaso-vasostomy (VV) or vaso-epididymostomy (VE). There are many factors that go into the decision for VE including gross and microscopic fluid characteristics and length of time from vasectomy. If pasty fluid or creamy fluid with no sperm parts is encountered from the testicular vas then the decision is often made for a VE. This typically occurs with a longer interval from vasectomy (> 10 years) but it can happen at any time. By 15 years about 50% of vasectomy reversals have at least one side being a VE (Mui et al., 2014; Fuchs and Burt, 2002; Fuchs et al., 2016).

A VV has an overall >95% patency and >70% pregnancy rate (Ostrowski et al., 2015a; Belker et al., 1991). There is wide variability on published VE patency and pregnancy rates but newer studies show a patency rate of over 70% with a clinical pregnancy rate of around 50% (Chan, 2013; Schiff et al., 2005). Sperm is seen back in the ejaculate sooner with a VV than VE (over 75% of men have patency by 3 months). Often it will take longer to return sperm back in the ejaculate after VE and at 3 months 23% have sperm back vs. 62% at over one year (Yang et al., 2007).

If the couple has previously had children together the likelihood of pregnancy is much higher at over 80% (Ostrowski et al., 2015b). One of the most important factors associated with vasectomy reversal success is female partner age (Fuchs and Burt, 2002; Gerrard et al., 2007). There is no difference in patency or pregnancy rates in a modified one vs. two layer closure but some surgeons continue to do two layer closures to maintain the microsurgical skillsets required for VE (Nyame et al., 2016).

The procedure involves identification of the vasectomy defect and cutting into the vasal lumen. After this there is an evaluation of the vasal fluid from the testicular side and the decision for VV vs. VE is made. Patency of the abdominal vas is evaluated with flushing the vas. A VV anastomosis is performed under the operative microscope utilizing 9-0 and/or 10-0 suture. If a VE is required, the epididymis is evaluated to identify full tubules (ideally as distal on the epididymis as possible to increase tubule size). A specific epididymal tubule is identified and the vas is connected most commonly using a Berger end to side technique (Berger, 1998) or an intussusception technique (Chan, 2013).

Identification of Testicular Sperm

Fine Needle Aspiration (FNA) Testicular Mapping

NOA men are some of the most difficult patients to treat as they can have very small areas of spermatogenesis in the testicle, which combined with the use of ICSI, can cause a pregnancy. Identification of which men have sperm is difficult. In 1965 the first FNA of the testicles were performed on infertile men (Beliveau and Turek, 2011). FNA mapping of the testicle has good correlation with testicular biopsy (Beliveau and Turek, 2011).

FNA mapping includes up to 18 sites (Fig. 1) on each testicle after a spermatic cord block. Each site is evaluated for sperm production and patients are identified as sertoli-cell only, minimal spermatogenesis, or extensive spermatogenesis. Sertoli-cell only patients have very low probability of success with micro-TESE and various adoption options are discussed. Patients with very minimal spermatogenesis are offered micro-TESE knowing that the likelihood of success is almost 100% of finding sperm. Finally, patients with extensive spermatogenesis patients are offered TESA/TESE (Fig. 2).

FNA testicular mapping is performed under local anesthesia in the office typically. It involves bilateral spermatic cord blocks and scrotal skin blocks. A 23-gauge, 1" needle is inserted into a cameco holder and inserted into the template location. Suction is applied and 5–10 mm in-and-out movements are performed. The suction is released after 10–20 needle passes at each site and tissue fragments are expelled onto a slide, smeared, and immediately fixed in 95% ethyl alcohol. These slides are subsequently evaluated for spermatogenesis.

A clinical care pathway has been developed and when all FNA sites/map showed sperm success at TESA was 98% finding sperm, if > 2 sites showed sperm then directed TESE success was 90% finding sperm, finally if < 2 sites showed sperm then the micro-TESE success was 81% finding sperm (Arredondo et al., 2004). This allows for improved patient counseling and resource allocation by the patients before IVF.

Fig. 1 A template FNA map of each testicle. Beliveau ME, Turek PJ. The value of testicular “mapping” in men with non-obstructive azoospermia. *Asian J Androl.* 2011;13(2):225–230.

Fig. 2 A schematic drawing of FNA mapping with the testicle wrapped for fixation and the template drawn on the scrotal skin. Beliveau ME, Turek PJ. The value of testicular “mapping” in men with non-obstructive azoospermia. *Asian J Androl.* 2011;13(2):225–230.

Testicular Sperm Aspiration/Extraction (TESA/TESE)

Removal of testicular tubules allows for pregnancy with the use of ICSI. TESA or TESE can be successfully used to remove testicular tubules for use with ICSI in certain azoospermic patients. This is successful in patients who have obstructive azoospermia (OA) (Schoor et al., 2002) and sometimes in patients with NOA. Published reports of success with NOA ranges from 17% to 45% success of finding sperm (Deruyver et al., 2014). If FNA mapping shows sperm in all locations with significant sperm production then TESA or focused TESE can be successfully performed (Arredondo et al., 2004).

The procedure is performed after spermatic cord and local skin block. A TESA uses a large bore angio-catheter connected with extension tubing to a syringe. Suction is applied through a syringe to extract testicular tissue. This can be performed multiple times following the lobular planes of the testicle allowing for adequate tubule removal. The advantage of TESA is that it utilizes a minimally invasive approach allowing for improved patient recovery. There is no need to close the scrotal skin or tunica albuginea as this will close in it's own. A TESE uses an incision through the scrotal skin, dartos, tunica vaginalis and tunica albuginea. This allows for easy removal of testicular tissue but does require closure of all the above listed layers with absorbable suture.

Percutaneous/Microsurgical Epididymal Sperm Aspiration (PESA/MESA)

There is controversy regarding differences in IVF/ICSI success using epididymal and testicular sperm. A 2004 meta-analysis (Nicopoullos et al., 2004) and a 2008 Cochran review (Proctor et al., 2010) failed to identify any success differences between testicular or epididymal sperm.

Sperm from patients with OA from prior vasectomy, congenital bilateral absence of the vas deferens, or infection, can be obtained from epididymis for use with IVF/ICSI. PESA can be performed in the office under local and has an 80%–100% successful sperm retrieval rate depending on the study. MESA is performed ideally in the operating room and has a 95%–100% successful sperm retrieval rate with 15%–42% total motility depending on the study but is more invasive (Bernie et al., 2013).

After spermatic cord and local skin block, a PESA uses a small butterfly needle (usually 19 or 21 gauge) inserted through the skin transversely into the epididymis. With application of gentle suction epididymal fluid can be removed. This fluid is evaluated in real time to identify motile sperm for use with IVF/ICSI.

A MESA is performed in the operating room utilizing an operating microscope. An incision is made through the scrotal layers down to the epididymis. The epididymis is then examined under the operating microscope to identify full tubules. These tubules are opened and the fluid evaluated for sperm for IVF/ICSI (Fig. 3).

Micro-testicular sperm extraction (micro-TESE)

First described by Schlegel in 1999 (Schlegel, 1999), and has quickly become the gold standard for patients with Klinefelter's syndrome, NOA, or patients with very small quantities of sperm found on FNA mapping. Results vary from 43% to 70% depending on the report and circumstances (Deruyver et al., 2014).

Fig. 3 Depiction of MESA.

Fig. 4 Isolated area from original Micro-TESE article showing area of normal tubules surrounded by atrophic tubules.

This procedure is performed in the operating room with the use of an operative microscope. The testicle is delivered and the tunica albuginea is opened. The testicle is then sequentially evaluated with the use of an operative microscope for full seminiferous tubules (Fig. 4). These tubules are minced and evaluated for sperm in real time for use with IVF.

Conclusion

There are three main objectives for surgical treatment for male infertility: improving fertility, identification and procurement of testicular sperm or restoration of fertility through vasectomy reversal. There are many different modalities of surgical treatment for male infertility patients and the discussion, decision making and patient factors are often complex and stressful.

Surgical Treatment of Varicocele

David T Greenwald and Samuel Ohlander, University of Illinois-Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Clinical varicocele Varicocele that is palpable on physical examination with or without Valsalva.

Inguinal Area of the groin or lower abdominal wall, with the thigh inferiorly, the pubic tubercle medially, and the anterior superior iliac spine superolaterally.

Laparoscopic Surgical technique where operations are performed through small incisions using a long, thin fiber-optic instrument.

Valsalva maneuver Exhalation against a closed airway. Often referred to as simply “Valsalva” and commonly described as “bearing down.”

Introduction

Varicocele is dilated and/or incompetent veins that drain blood from the testicle, and has been associated with impairment of spermatogenesis and Leydig cell function. It is thought that venous pooling results in significant elevations in testicular temperature leading to progressive and duration-dependent testicular impairment. Varicoceles are found in ~15% of general population, 35% of men with primary infertility, 75%–81% of men with secondary infertility ([World Health Organization, 1992](#)).

Indications for Intervention

Therapeutic management of a varicocele is indicated for a symptomatic, clinically palpable varicocele. Classification of grade is based upon whether or not Valsalva maneuver is necessary for palpation, though all palpable varicoceles are considered clinically relevant ([Table 1](#)). Subclinical varicoceles, or those that are not palpable on exam but merely identified via imaging, have not been found to be clinically relevant and thus repair is not indicated ([Jarow et al., 1996](#)). Primary symptoms may be infertility, either primary or secondary, or varicocele induced pain. For those with infertility, most often there is a degree of spermatogenic dysfunction as identified by decreased counts on semen analysis. The classic stress pattern from a varicocele is oligoasthenoteratospermia, which includes decreased counts (oligo), poor motility (astheno), and poor morphology (terato) ([Saypol, 1981](#)). However, not all seminal abnormalities are present in each case. Management is also indicated in certain patients with varicocele induced pain refractory to more conservative measures. Counseling plays an important role in the management of varicocele-induced pain, as surgical repair does not guarantee resolution of the pain ([Pasqualotto et al., 2006](#)). Additionally, though very controversial at this point in time, the application of management to age related androgen deficiency has been described. The dose dependent impairment of Leydig cell dysfunction has been demonstrated when comparing testosterone levels in men with varicoceles to age matched controls.

In the pediatric population, varicocele repair is indicated when there is a palpable varicocele with testicular size discrepancy of greater than 15% between the affected testicle and the contralateral testicle ([Lipshultz and Corriere, 1977](#)). The affected testicle may undergo catch-up growth after repair of the varicocele ([Kass and Belman, 1987](#)). As the noxious effect of varicocele on spermatogenesis is dose related, varicolectomy in the adolescent is also considered to prevent future fertility issues. As it is uncertain which pediatric patients with varicoceles will have a fertility problem, repair in this scenario is still controversial.

Management options include observation, surgical intervention (scrotal, retroperitoneal, laparoscopic, inguinal, subinguinal, microsurgical), and non-surgical radiographic options (percutaneous venous occlusion, antegrade sclerotherapy).

Table 1 Varicocele grading ([Dubin and Amelar, 1970](#))

Subclinical	Not present clinically, abnormality only seen on ultrasound
Grade 1	Only present clinically when man performs Valsalva maneuver
Grade 2	Easily palpable, not visible
Grade 3	Visible through scrotal skin, easily palpable

Special Considerations

Some men who present for vasectomy reversal are found to have significant varicoceles. Varicocelectomy in this scenario presents a challenge. With ligation of the spermatic veins in varicocelectomy, the vasal veins function as the only remaining venous return, but after vasectomy the vasal veins are likely compromised. One must assure to preserve some avenue for venous return, as well as the testicular artery (the primary remaining blood supply). This is accomplished with the preservation of the cremasteric veins using the microsurgical technique. The recurrence rate, however, was noted to be higher with preservation of the cremasteric veins and periaarterial veins, when compared to non-vasectomized men where these veins were ligated. Instead of performing simultaneous vasectomy reversal and varicocelectomy, a safer approach is to proceed with vasovasotomy or vasoepididymostomy first, assess the semen quality post-op, and perform varicocelectomy at least 6 months later if necessary. This allows for arterial and venous neovascularization across the anastomotic line.

For infertile couples considering assisted reproductive techniques, there is some evidence varicocelectomy improves outcomes. A study on varicocelectomy before intrauterine insemination (IUI) showed that although there was a slight decrease in sperm motility after varicocelectomy, there was a significant increase in pregnancy and live birth rates. This retrospective review of couples with male factor infertility that underwent IUI included men with varicocele and abnormal semen parameters, and compared outcomes of varicocelectomy versus no varicocelectomy (Daitch et al., 2001). Similarly, infertile couples where the male had a varicocele who used IVF/ICSI have shown improved pregnancy and live birth rates after varicocelectomy when compared to the same cohort without varicocelectomy (Kirby et al., 2016).

As it takes 3 months for sperm to mature, there is a time lag after varicocelectomy to observe for improvement in semen quality. For older couples with infertility, this delay must be factored into decision-making on whether or not to pursue treatment, as assisted reproductive techniques may yield more immediate results without surgical repair of the varicocele. This is of particular importance to couples in which the female has advanced maternal age and/or limited ovarian reserve.

Surgical Intervention

Scrotal

Scrotal approaches for varicocelectomy have been described historically though rarely play a role in present day practice. Scrotal varicocelectomies involve a transscrotal incision with dissection down to the spermatic cord, isolation of the vasculature, and ligation and/or excision of the varicocele. These approaches ultimately were not successful as the testicular artery is entwined with the pampiniform plexus at the level of the scrotum, and there are a large number of veins necessary for complete treatment, often leading to incomplete ligations and high recurrence rates (see Table 2). Given the intimate venous/arterial relationship, testicular atrophy often resulted from damage to the testicular artery.

Open Retroperitoneal

The retroperitoneal approach for varicocelectomy involves ligation of the internal spermatic veins proximally, near the left renal vein or IVC. The incision is at the level of the internal ring, dissection through the external and internal oblique muscles, to achieve exposure of the testicular artery and veins in the retroperitoneum near the level of the ureter. At this point the artery is distinct and there are limited venous tributaries converging together to form the gonadal vein.

This approach is more commonly used in pediatrics, but largely has been replaced by more minimally invasive therapeutic options. It may be advantageous in patients with previous inguinal surgery, where there is a higher risk of testicular artery or ilioinguinal nerve injury. This approach has a few notable technical challenges when compared to alternative approaches. The approach involves working in a deep hole. The testicular artery can be as small as 1 mm in diameter and, thus, hard to identify. Use of Doppler is paramount, as it is in all surgical approaches to varicoceles. Additionally, the veins have to be identified and ligated within the

Table 2 Complication rates after varicocelectomy

<i>Surgical technique</i>	<i>Recurrence (%)</i>	<i>Hydrocele (%)</i>
Retroperitoneal ^a	15–45	3.0–6.4
Open inguinal ^b	5–15	3–30
Microscopic inguinal/subinguinal ^c	0.6–1.0	1.3–1.6
Laparoscopic ^d	3–18	12–22
Radiographic ^e	4–11	0

^dGlassberg et al. (2008), Al-Said et al. (2008).

^eMitchell et al. (1985), Matthews et al. (1992).

retroperitoneum as inability to fully mobilize the vessels leaves the surgeon unable to deliver them through the wound. It is also challenging to correctly identify and preserve lymphatics, resulting in a post-op hydrocele rate of 7%–33% (see [Table 2](#); [Szabo and Kessler, 1984](#)).

The rate of varicocele recurrence after the retroperitoneal approach is ~15% (see [Table 2](#); [Watanabe et al., 2005](#)). It has been reported higher in pediatrics, with a recurrence rate of 15%–45% ([Reitelman et al., 1987](#)). One hypothesis is that the fine periaarterial plexus of veins around the testicular artery, which have been shown to communicate with the larger spermatic veins, is spared, resulting in retrograde flow and pooling of venous blood after ligation of the other larger tributaries. [Kass and Marcol \(1992\)](#) described intentional ligation of the testicular artery and the periaarterial veins to reduce recurrence rate. In children, intentional arterial ligation at time of retroperitoneal varicolectomy can lead to reversal of varicocele associated testicular atrophy, with collateral arterial supply supporting the testicle. Another potential source of recurrence is the presence of parallel inguinal or retroperitoneal collateral. These veins exit the testis and bypass the ligated retroperitoneal vein(s), re-joining the internal spermatic vein proximal to the ligation. A third hypothesized source of recurrence is dilated cremasteric veins, as these are not identified via the retroperitoneal approach and have been implicated as a cause of recurrent and persistent varicocele after surgical repair.

Laparoscopic

The laparoscopic varicolectomy, similar to open retroperitoneal approach, involves ligation of the internal spermatic veins proximally, near the left renal vein or IVC. Exposure of the internal ring is obtained via transperitoneal laparoscopic access. Visualization of the internal spermatic veins, the vas deferens, the testicular artery, and nearby lymphatics allows for careful ligation of the veins while preserving the neighboring structures. Sparing the lymphatics has led to reduction in post-op hydrocele formation in pediatric patients (see [Table 2](#); [Glassberg et al., 2008](#)).

The reported rate of recurrence for all patients is 2.9%–18% (see [Table 2](#); [Glassberg et al., 2008](#)). An advantage to the minimally invasive approach is that the same laparoscopic access can be used for bilateral varicocele repair. Laparoscopic single site has also been described for children and adults, with shorter post-op pain and recovery time with similar post-op semen quality and complication rate. This technique carries additional risks versus open technique, including damage to abdominal viscera. Furthermore, minimally invasive techniques carry increased cost when compared to open approaches, and modifications utilizing the operative robot have increased costs over that of standard laparoscopic management.

Inguinal

The open inguinal and subinguinal approaches allow access to the spermatic cord structures with the benefit of improved surgical visualization. The cord structures are mobilized and delivered through the incision to better identify the veins, artery, vas deferens, and lymphatics. In addition, the external spermatic and gubernacular veins can be identified and ligated. These can otherwise bypass the cord and be a potential source of recurrence. The traditional inguinal approach involves an incision over the inguinal canal, dissection through the external oblique aponeurosis, delivery of the spermatic cord by freeing cremasteric attachments, identification and isolation of the cord structures to ligate the spermatic veins and preserve the vas deferens/testicular artery/lymphatics. Incidence of post-op hydrocele is 3%–15% (see [Table 2](#); [Szabo and Kessler, 1984](#)), often attributed to inadvertent ligation of lymphatics. The rate of testicular artery injury is unknown, but as it is the largest artery to the testicle, injury can lead to testicular atrophy, even with preservation of the vasal and cremasteric arteries.

Surgical modification with utilization of the operative microscope for varicolectomy has led to marked improvement in rates of post-op hydrocele formation due to better identification and preservation of lymphatics, with a reported rate of post-op hydrocele less than 1% (see [Table 2](#); [Cayan et al., 2000](#)). In addition, the testicular artery can be better identified and preserved. Again, utilization of the microdoppler is paramount in classifying the vasculature correctly. The inguinal approach is preferred in pediatrics, solitary testes, tight/low external ring, short cord, or high lying testis. In pediatric patients, the testicular artery is especially small and thus harder to identify. Approaching the artery inguinally increases the surgeon's ability to correctly identify it as there have been limited branches compared to a more distal approach. Additionally, there are fewer venous branches as tributaries have coalesced to an often more manageable number of veins that require management.

The procedure starts with locating and marking the location of the external ring. The incision is made at the level of the external ring and carried down through Campers and Scarpas fascia using blunt dissection and electrocautery. In the inguinal approach the external oblique aponeurosis is cleaned off and opened to the external ring, parallel to the fibers. The ilioinguinal nerve is identified and gently swept away from the cord. The spermatic cord is then gently freed up and delivered through the incision by releasing the cremasteric attachments. Once delivered, the cord may be encircled with a penrose drain to elevate it from the canal, and also can be used to exclude the ilioinguinal nerve from the operative field.

Once the cord is delivered, the operating microscope is brought over the surgical field. Under magnification, the external and internal spermatic fascias are opened, and the cord is inspected using the microdoppler to identify the arteries. Identified arteries are dissected free from surrounding structures, and encircled with a vessel loop for identification. When an artery is difficult to identify, it is often found adherent to the underside of a large vein. Also the testicular artery can go into spasm from surgical manipulation, rendering the microdoppler ineffective. Application of papaverine irrigation, a vasodilator, can restore normal arterial pulsations and aid in identification. Veins are stripped free of lymphatics, and ligated with clips or 4-0 silk. Bipolar cautery may be utilized for smaller veins, especially those adherent to the testicular artery. The vas and the accompanying pair of vasal veins are

preserved. If the vasal vein is dilated beyond 3 mm, it is dissected free and ligated, as only one vasal vein is sufficient for testicular venous return. Cremasteric arteries are found in the majority of cases, usually between a pair of accompanying veins. The veins are to be ligated, and the artery preserved. At the conclusion of the dissection, the cremasteric muscle fibers, testicular arteries, cremasteric arteries, the vas and vasal vessels, lymphatics, and nerves are preserved.

Some surgeons elect to deliver the testicle in order to directly visualize and ligate scrotal or gubernacular collateral veins, as these have been identified as the cause of up to 10% of varicocele recurrence. With gentle upward traction on the cord, the testis can be delivered through the incision to directly visualize all venous drainage from the testicle. Once the testicle is delivered, external spermatic veins and gubernacular veins can be identified and ligated. If an incidental hydrocele is identified when the testicle is delivered, as is the case in 15% of varicoceles, it can be repaired concurrently. Of note there is an immediate and transient elevation of venous pressure after varicolectomy which increases the chance of post-op hematoma.

The external oblique is closed with running 3-0 absorbable suture. Then for either approach, closure of Scarpas fascia and Campers fascia with interrupted 3-0 absorbable suture. Skin closure with 4-0 or 5-0 running subcuticular monofilament absorbable suture, reinforced with steri strips or surgical skin glue. Patient is fitted with scrotal support and fluff dressing.

Subinguinal

In the subinguinal approach, the technique is simply a modification of the inguinal technique described above. The incision is made inferior to the external ring and access to the spermatic cord is obtained without opening the inguinal canal. The cord is identified, pulled cephalad, and delivered through the incision. Identification and ligation of the vessels proceeds as done in the inguinal approach. Given that this approach precludes the need for opening the external oblique aponeurosis, it often leads to less post-op pain and a more rapid recovery. However, at the subinguinal level there are more venous tributaries, and often the artery has divided into smaller branches. In addition the arterial pulsations can be dampened due to compression by the edge of the external ring, so care must be taken to assure the cord is investigated under relaxed exposure. Due to these complexities, the operating microscope is generally used for this approach. The subinguinal approach is preferred in patients with prior inguinal surgery, obesity, lax/high external ring, or circumstances of a long cord with a low-lying testis. After previous inguinal surgery, the spermatic cord is often scarred and adherent to the external oblique aponeurosis, thus placing the cord at risk of injury when opening the fascia in the inguinal approach.

Radiographic

Radiographic options also have been described for diagnosis and treatment of varicoceles. Prior to widespread use of microsurgical technique, intraoperative venography previously was used to better identify venous collaterals, which, if left untreated, could be the source of varicocele recurrence.

Radiographic balloon or coil occlusion of internal spermatic veins can be used for treatment of varicocele. It involves access to the femoral or internal jugular vein, via a small cut down incision w/local anesthesia, and cannulation of the internal spermatic veins to deploy the occlusion device. Sclerotherapy can be employed for occlusion of smaller collaterals. Successful treatment was accomplished in 75%–90% of patients undergoing radiographic occlusion with a 4%–11% rate of recurrence (see [Table 2](#); [Matthews et al., 1992](#)). There is no risk of testicular artery injury with this approach. Disadvantages of the procedure include a relatively high rate of initial failure (10%–25%), increased length of procedure (1–3 h for radiographic occlusion versus approximately 45 min for surgical repair), need for radiation exposure (which infertile patients often seek to avoid), and rare serious complications (migration of coil/balloon into renal vein causing loss of kidney, or pulmonary embolism of coil/balloon, femoral vein thrombosis) ([Matthews et al., 1992](#)).

Anterograde scrotal sclerotherapy for treatment of varicocele was originally described by Tauber in 1988 in Germany. It involves access via cannulation of a scrotal vein, with similar rates of success and failure as radiographic balloon dilation ([Minucci et al., 2004](#)).

Complications

Hydrocele is the most common complication after varicocele, ranging from 3% to 33% depending on the technique (see [Table 2](#)). [Szabo and Kessler \(1984\)](#) analyzed the protein composite of the hydrocele fluid and demonstrated that lymphatic obstruction was the likely source of post-varicolectomy hydrocele formation. The addition of the operating microscope enables a surgeon to improve the identification and preservation of lymphatics, which greatly reduces the risk of post-op hydrocele ([Glassberg et al., 2008](#)). There is no current data to suggest post-varicolectomy hydroceles negatively impact fertility, and, thus, they are managed the same as simple hydroceles.

The testicular artery supplies roughly two-thirds of the testicular blood supply, with the remaining third from collateral blood flow from the cremasteric and vasal arteries. Testicular artery injury can lead to testicular atrophy and loss. The true rate of testicular artery injury is unknown. The usage of operating magnification with a microscopic Doppler vastly improves the identification of the testicular artery and decreases the rate of injury. Children likely have a better potential for compensatory increased blood flow to the vasal and cremasteric vessels when compared to adults, and are less likely to have testicular atrophy after testicular artery ligation.

Recurrence of varicocele after varicolectomy ranges from 0.6% to 45% (Al-Kandari et al., 2007), but more specifically, can be stratified by operative approach (see Table 2). Recurrence after retroperitoneal reported 15%–45%, conventional inguinal 5%–15%, microscopic inguinal/subinguinal 1%, laparoscopic 3%–15%, radiographic 15%–25%. Recurrence in essence is from residual venous collaterals—periarterial, parallel inguinal or retroperitoneal, transscrotal have all been reported. The microsurgical approach with delivery of the testis, to address scrotal collaterals, lowers the incidence below 1%.

Results

Varicolectomy for male factor infertility results in significantly improved semen analysis in 60%–80% of men, and reported pregnancy rates of 20%–60% after varicolectomy (Marmar et al., 2007). In one review of recent studies on varicolectomy in male factor infertility, Richardson et al. found that the majority of studies showed an improvement in sperm density, motility, and morphology after varicolectomy. Despite the improvement in semen parameters, the reported average pregnancy rate was 39.35%, which is similar to previously reported fecundity outcomes (Richardson et al., 2008). A randomized trial of infertile men with varicoceles demonstrated a marked improvement in pregnancy rate 1-year post-op: a pregnancy rate of 44% in surgery group versus 10% in an untreated control group (Abdel-Meguid et al., 2011). For azoospermic men with palpable varicocele, undergoing a microsurgical varicolectomy lead to a return of sperm in 60% of subjects (Matthews et al., 1998). When comparing laparoscopic to microsurgical technique, one trial did not show any difference in fertility outcome (Bryniarski et al., 2017). However, a meta-analysis comparing microsurgical, laparoscopic, and open approaches showed significantly better pregnancy rate and semen parameters with the microsurgical approach (Yuan et al., 2017). For patients with varicocele pain, the majority of patients report improvement after varicolectomy. Yaman et al. (2000) found that 88% of patients had complete resolution of their pain. Also, varicolectomy in infertile men with low testosterone have resulted in improvement in serum testosterone levels.

Conclusion

The treatment of varicocele has improved overtime with technological advancement and the addition of new approaches, most recently the microsurgical technique. During this evolution there has been a measured improvement in outcomes and decrease in complications.

Introduction

Male Reproductive Tract Anatomy

The male reproductive tract is comprised of multiple parts, including the paired testes, the epididymis, vas deferens, seminal vesicles, ejaculatory ducts, and prostate. All these components serve to produce, transport, and deliver viable sperm to the female reproductive tract, which allows for human reproduction.

The testes are paired ovoid organs located in the scrotum, with a normal sized testis ranging from 15 to 25 mL in volume. Sperm are produced within numerous coiled tubes known as seminiferous tubules in the testis. Within the seminiferous tubules lie germ cells (spermatogonia, spermatocytes, and spermatids) and Sertoli cells which support the sperm maturation process. Aside from these tubules, there are testosterone producing cells in the testis called Leydig cells. The sperm after being produced and undergoing a maturation process are released from the seminiferous tubules to subsequently exit the testes for transportation through the epididymis.

The epididymis is a comma shaped structure composed of thin tubules that cups the posterior aspect of the testis. The sperm as they travel through the epididymis undergo numerous changes including the development of functional motility and the capacity to fertilize oocytes.

After maturing in the epididymis, the sperm enter the vas deferens, a tubular structure ranging 30–35 cm in length that carries sperm from the epididymis to the ejaculatory duct deep within the male pelvis. The external diameter of this structure ranges from 1.5–3 mm, with an internal (lumen) diameter ranging from 0.2–0.7 mm in diameter. It is generally easily palpated within the scrotal skin.

Fluid from the vas deferens, epididymis and testis is then joined by secretions from the seminal vesicles (SV) and prostate to form the ejaculate. From 65% to 80% of the volume of ejaculate fluid is made by the SV, while approximately 25% arises from the prostate. These secretions aid in support the sperm as they enter the female reproductive tract ([McDougal et al., 2011](#)).

Means of Male Birth Control

There are numerous methods of contraception, or preventing pregnancy, involving the male reproductive tract.

One of the simplest methods for contraception involves interrupting sexual activity and withdrawing the penis prior to ejaculation. This is known as coitus interruptus or the withdrawal technique. Studies have shown a failure rate of up to 24% per year with this method ([Black et al., 2015a](#)).

Another method of contraception is through a barrier method such as a condom. A condom is a flexible sheath that is slipped over the penis prior to intercourse. The sheath then prevents any ejaculated fluid from entering the female partner's body. Barrier contraception also has the added benefit of preventing the transmission of sexually transmitted diseases. The failure rate of condoms are 18% per year with typical use ([Black et al., 2015b](#)).

Vasectomy is the only present form of permanent male contraception. This procedure involves physically disrupting the vas deferens, blocking passage of any sperm from the testes into the ejaculatory duct. This procedure is usually done under local anesthetic and has an early failure rate of 1%–2% ([Sharlip et al., 2012](#)). After no sperm has been demonstrated on a semen analysis postvasectomy, late failure rates are 1 in 2000. This is generally a very well tolerated and safe procedure with no impact on sperm production, sexual functioning or testicular function.

History

The history of the vasectomy procedure is marred by controversy, with applications ranging from therapeutic, eugenic, to punitive ([Sheynkin, 2009](#); [Kim and Goldstein, 2009](#)). The first reported vasectomy for contraception was reportedly performed in 1899 by Dr. Harry Sharp, the chief physician at the Indiana Reformatory. This procedure was performed on an inmate as an alternative to stop excessive masturbation. A semen sample was performed after this and the inmate was found to be sterile ([Sheynkin, 2009](#)). Early on, aside from contraception, there were medically questionable indications for vasectomies, including preventing inflammation of the epididymis in the setting of prostate enlargement, or for purposes of mental rejuvenation. Furthermore, surgical sterilization was once used on the criminal, the insane or perverse, to prevent them from producing offspring. Mass sterilization was also performed by the Nazis during World War II for the purpose of racial limitation or extermination. Due to these political, religious, and medical implications, considerable interest in the vasectomy reversal (VR) procedure was raised in the 1940s, though this was still fraught with technical challenges and low success rates.

One of the first reported cases of a re-anastomosis of severed vasa deferens was by J. Lynn Thomas, a consulting surgeon from Cardiff in 1904 ([Thomas, 1904](#)). He described a patient that had both vas severed by his wife in a semicomatose state after a fit of

jealousy. An oblique union of the testicular vas to the urethral vas was described. The procedure resulted in a pregnancy, thus was considered a success.

Subsequently in 1919, Quinby published a report on a successful vasovasostomy in a man who had purposely undergone bilateral vas resections 8 years prior (O'Connor, 1948). This repair was repaired over a strand of silkworm gut as a stent and left in place for 10 days. Vincent O'Connor, the urologist who assisted Quinby, subsequently published on a series of 14 vasectomized patients utilizing the same technique, resulting in a patency rate of 64%.

Numerous techniques soon arose on macroscopic vas anastomoses, with varying suture materials and certain practices using intraluminal stents consisting of suture or steel wires. Up to a 50%–70% patency rate was reported in literature.

Sherman Silber, an American urologist was the first to report on the use of a microsurgical vasovasostomy (VV) in the USA in 1975 (Kim and Goldstein, 2009). He performed a two-layer anastomosis using 9–0 and 10–0 nylon sutures. Earl Owen, an Australian plastic surgeon also independently performed the first VV in Australia at around the same time. The development of the microsurgical technique has laid the foundation for modern microsurgical approaches.

Re-Establishing Fertility Following a Vasectomy

With the vasectomy established as a safe, effective, and voluntary method of birth control, approximately 500,000 vasectomies are performed per year in the United States (Eisenberg et al., 2009). Out of this population, up to 6% of this population will consider some technique to re-establish their fertility (Potts et al., 1999). Other causes of a “vasectomy” such as hernia repairs, trauma and infections are far less common causes of vasal obstruction.

Consideration to re-establish fertility following a vasectomy has been found to be most frequently requested due to divorce and remarriage. Other changes in social circumstances including death of a spouse, death of a child, or a change of mind about family size are also reported reasons for vasectomy reversal (Potts et al., 1999).

Re-establishing fertility following a vasectomy/vasal obstruction could be accomplished by a

- (1) vasectomy reversal or
- (2) sperm retrieval from the testis or epididymis coupled with injection of the sperm into an oocyte (intra-cytoplasmic sperm insertion or ICSI),

How to Choose Between a Vasectomy Reversal or Sperm Aspiration with ICSI to Re-Establish Fertility: Risks and Benefits

The patients choose based on their assessment of risks of the procedures, costs, success rates and personal preferences. Overall, pregnancy rates following a vasectomy reversal are between 40% and 90% (see below) while pregnancy rates following one cycle of sperm aspiration with ICSI are 16%–40% (Pavlovich and Schlegel, 1997). Based strictly on the medical cost per live birth, Schlegel et al. found that a vasectomy reversal had an average cost of \$25,475 versus \$72,521 for sperm retrieval-ICSI, factoring the costs of potential complications as well as delivery costs (Pavlovich and Schlegel, 1997). However, patients often choose between the two procedures not based on the cost per child alone, but on personal preferences (such as **timing**: pregnancies are usually earlier with ICSI than with vasectomy reversal or **risk assessment**: competing risks of more surgery with a vasectomy reversal compared to a sperm aspiration, but higher risks with a pregnancy established through ICSI than a spontaneous pregnancy).

A balanced presentation of the birth rates, risks of the procedures and costs helps couples decide to choose either vasectomy reversal or sperm aspiration with ICSI.

Prediction of Outcomes of VR Prior to Surgery

The main measures for technical and functional success in VV are patency rates and pregnancy rates respectively. In the era of microsurgical reconstruction, outcome studies for VV have shown patency rates ranging from 75% to 100% and pregnancy rates from 45% to 73% (Herrel et al., 2015; Belker et al., 1991). A recent study on microsurgical vasovasostomy for vasectomy reversal, looked at a total of 31 studies conducted from 1980 until 2014 and examined outcomes (Herrel et al., 2015). An overall patency rate of 89.4% was noted and a pregnancy rate of 73% was calculated from grouping all of these studies together, though these numbers should be interpreted with caution due to the varied definitions of patency and pregnancy.

Multiple studies have further identified possible factors that affect the success of VV. These can be further divided into factors prior to the surgery (preoperative factors) and factors identified at the time of surgery (intraoperative factors).

Preoperative factors that have been studied include the time elapsed since vasectomy (obstructive interval), prior VV, prior fertility, prior surgery in the groins, length of the vasal stump, and age of the partner.

One of the largest and most comprehensive studies on vasectomy reversal was the Vasovasostomy Study Group (VVSG), a multi-center, multi-surgeon study that aimed to look at outcomes of the procedure (Belker et al., 1991). In this study, one of the factors that independently influenced success rates of the vasectomy reversal from this study was obstructive interval. This study showed that if the VV is performed within 3 years from vasectomy, the patency rate was as high as 97%, with a pregnancy rate of 76%. At more than 15 years out from the vasectomy, the patency rate dropped to 71% and the pregnancy rate decreased to 30%.

The presence of prior vasectomy reversal also negatively impacts both patency and pregnancy rates, with a higher chance of converting to a more complex reconstruction, such as connecting the tubules in the epididymis to the vas directly in a procedure called

an vasoepididymostomy (VE) (Hollingsworth et al., 2007). The VVSG also found that in patients with repeat reversal procedures, patency rates dropped from 86% to 75% and pregnancy rates fell from 52% to 43% (Belker et al., 1991). Another study by Hernandez and Sabanegh found that there was a unilateral VE rate of 73% in a repeat vasectomy reversal procedure versus 4% in the initial procedure. They also found that patency and pregnancy rates were impacted with a repeat procedure, at 79% and 31% respectively (Hernandez and Sabanegh, 1999).

The length of the postvasectomy testicular vasal remnant has also been found to impact reversal success rates. One study showed that a testicular vasal remnant length of less than 2.7 cm predicted for an intraoperative finding of no whole sperm in the vasal fluid. In this study, patients with whole sperm found intraoperatively were found to have patency and pregnancy rates of 90% and 54% respectively, versus 60% and 30% respectively in those with no whole sperm found (Witt et al., 1994).

One of the most significant factors affecting pregnancy rates after vasectomy reversal is the age of the female partner. One study on vasectomy reversals found that though postoperative patency remained similar, pregnancy rates dropped from 56% to 14% if the female partner was 40 years of age or older (Gerrard et al., 2007). This should be taken into account when counseling patients about vasectomy reversal success rates, especially since it takes on average 12 months for conception to occur after a successful reversal.

The presence of a sperm granuloma, a lump created by extravasated sperm after the vasectomy, has been found to be an independent predictor of vasectomy reversal success, with a reported patency rate of 95% in men with at least a unilateral sperm granuloma versus 75% in those without. It is thought that sperm extravasation from the testicular end reflects venting of high pressure away from the epididymis. This has been shown to have a favorable impact on VV patency rates (Boorjian et al., 2004). Operative scars from prior scrotal and groin surgeries should also be assessed, as these may suggest previous, inadvertent injury to the vas.

Numerous intraoperative factors that predict success rate have been studied. These include the length of the vas left on the testicular end, the presence of an inflammatory response to the sperm after vasectomy (sperm granuloma), and surgeon experience.

One of the key intra-operative findings to provide prognosis of success of a VR is the finding of the “quality” of fluid and the microscopic findings of the vasal fluid.

As per the landmark VVSG study, the color and quality of the fluid expressed from the testicular end of the vas deferens can often predict microscopic findings of the vasal fluid (Belker et al., 1991). The results of both gross appearance and microscopic examination will inform the surgeon of how to proceed with the procedure. In the study, a grade ranging from 1 to 5 was given based on microscopic findings of the vasal fluid, with grade 1 showing mainly normal, motile (moving) sperm, grade 2 showing mainly normal, nonmotile sperm, grade 3 showing mainly sperm heads, grade 4 showing only sperm heads, and grade 5 showing no sperm at all. The patency rate and pregnancy rates based on fluid grading were also outlined in the VVSG study, with good success rates with VV for grades 1–4 (Table 1).

Vasectomy Reversal to Treat Postvasectomy Pain Syndrome

In patients with prior vasectomy, 1%–2% of patients will have chronic (lasting greater than 3 months) postprocedural scrotal pain or discomfort that interferes with quality of life and requires medical attention (Tan and Levine, 2016). The onset of this condition can range from 7 to 24 months after the procedure (Leslie et al., 2007). Signs and symptoms of this postvasectomy pain syndrome (PVPS) can include point tenderness of the vas and/or epididymis, induration or enlargement of the vas, and pain with straining and dyspareunia (Tan and Levine, 2016). This etiology for this condition still remains unclear, but one possible explanation is thought to be vasal congestion and backpressure (Nangia et al., 2000). It then seems intuitive that a vasovasostomy, which eliminates the pressure from vasal obstruction, would help with PVPS. Though current data is mostly from small series at single institutions, several studies have shown improvement in close to 100% of patients undergoing vasovasostomy for PVPS and complete resolution of pain in 50%–70% of patients (Nangia et al., 2000; Polackwich et al., 2015; Horovitz et al., 2012).

Procedure

The vasectomy reversal is one of the most technically demanding procedures in urology, requiring precise alignment of the inner diameter of the vas deferens. Given the delicate nature of the structures involved and the degree of precision required, optical magnification is necessary. Though some surgeons perform macrosurgical anastomoses with magnifying optical loupes, it is generally accepted that microsurgical reconstruction produces superior outcomes, thus microsurgical training with an operating microscope is recommended.

Table 1 Reported patency and pregnancy rates based on vasal fluid quality (Belker et al., 1991)

<i>Vasal fluid quality</i>	<i>Patency rate</i>	<i>Pregnancy rate</i>
Grade 1 (most normal, motile)	94.3%	63.2%
Grade 2 (most normal, nonmotile)	90.5%	53.9%
Grade 3 (most heads without tails)	95.7%	50%
Grade 4 (only heads without tails)	75.3%	44.3%
Grade 5 (no sperm)	60.2%	30.8%

With the vasovasostomy procedure itself, the basic surgical principles that apply to all connections of tubular structures remain the same. First off, precise realignment of the inner diameter of the vas is paramount. The alignment of the inner, or mucosal, layer of the vas deferens minimizes the risk of leakage of sperm and subsequent inflammatory reaction. The diameters of the testicular end and abdominal ends of the vas deferens may be markedly discrepant, especially with prolonged obstructive intervals, making this challenging. Furthermore, unlike blood vessels, there are no clotting factors or platelets present in vasal fluid, making a leak-proof connection all the more important, and entirely dependent on the quality of the suturing.

Other principles include careful, atraumatic handling of the ends of the vasa, with little room for error as improperly placed sutures may damage the ends, and improper tension on the sutures can easily tear the mucosa. It is also important to preserve the blood supply of the ends of the vas, supplied by a network of small blood vessels that run along the surface. Ideally the ends of the vas that are connected together should exhibit some bleeding, reflecting good blood supply which is necessary for proper healing. The connection between the vas also needs to be performed in a tension free manner. Studies have shown that with connections under tension, sperm may return in the ejaculate transiently, but ultimately the connection will scar down again and fail.

Numerous techniques exist for vasectomy reversals and ultimately the technique chosen depends on surgeon experience as well as intra-operative factors. The basic tenets of vasectomy reversal remain the same, with the aim to reestablish patency from the testicle to the ejaculatory duct.

In all cases of prior vasectomy, there will be a buildup of scar tissue at the site where the vas deferens was occluded. This scar is usually readily palpable through the scrotal skin. The approach to the opening in the scrotum varies (from mini-incision approaches to larger openings), but this approach does not seem to change the success rates of the surgery. Bilateral vertical scrotal incisions are then made at the level of the scar. A ring clamp can be used to immobilize the scar tissue and overlying skin to aid in dissection. Both the testicular and abdominal ends of the vas must subsequently be mobilized away from the scar. It is important to isolate a portion of the vas away from the scar that is healthy, this is the best chance to ensure a good quality connection. Once this is performed, fluid should be milked out from the testicular end and examined microscopically for the presence of sperm.

Once sperm is confirmed in the vasal fluid, the abdominal end of the vas may be evaluated by irrigating the cut end with sterile saline using a blunt, 25-gauge IV catheter tip. The free flow of fluid into the abdominal vas confirms patency. Most surgeons do not routinely perform a vasogram while performing a VR.

The two most common microsurgical techniques used to connect the ends of the vas deferens are either the modified one-layer anastomosis or two-layer anastomosis. Most surgeons will use nylon suture material for the connection as it is less likely to cause inflammation of the surrounding tissues. It is also important to use bipolar cautery to seal off bleeding vessels intraoperatively. Bipolar cautery is a method of electrical energy delivery to the tissues where the current runs only from one side of a pair of forceps to the other side. This allows for concentrated energy delivery to the target tissues and minimizes scattering of energy to undesired areas. This is especially important in vasectomy reversals as this helps to preserve the integrity of the tissues at the ends of the vas.

The two-layer anastomosis was the initial microsurgical technique described by both Silber and Owen ([Kim and Goldstein, 2009](#); [Silber, 1977](#)). In this technique, the inner diameter of the vasa are connected together first in a single layer comprising of approximately six circumferential sutures. The needle in each of these sutures enters the lumen of the vas and exits out partway along the cut edge, bringing together only the inner diameter. Subsequently, a second layer of circumferential sutures are placed just in the outer muscular layer of the vas deferens, bringing the outer diameter together.

A modified one-layer technique was subsequently first described by Ira Sharlip, whereby a full thickness suture is placed through the vasa at the 12, 3, 6, and 9 o'clock positions ([Sharlip, 1981](#)). The intervening spaces were then closed with a suture placed through the muscular layer only. This technique was found to shorten the OR time for the case.

As per the VVSG study, they compared the modified 1 versus 2 layer anastomoses and no differences in patency were discovered ([Belker et al., 1991](#)) ([Fig. 1](#)).

If no sperm is found on microscopic examination, even after flushing out the testicular end of the vas with a syringe tip (Grade 5), then vasoepididymostomy should be considered, though good results can still be obtained if the quality of the fluid is watery ([Belker et al., 1991](#)) ([Table 2](#)).

The epididymis should be carefully inspected under the microscope to look for dilated epididymal tubules, which are enlarged ducts within the epididymis that suggest an obstruction closer to the testicle. If dilated epididymal tubules are visualized, the abdominal vas deferens should be connected to an epididymal tubule, a procedure known as the vasoepididymostomy.

The vasoepididymostomy is one of the most technically demanding procedures in microsurgery. Absolute precision is necessary in order to create a connection between the diameter of a dilated epididymal tubule measuring 0.15–0.2 mm to the abdominal end of the vas deferens. In this procedure, a small opening is made in the tunica of the epididymis, revealing numerous epididymal tubules. After this, the end of the vas deferens is anastomosed to the side of the epididymal tubule using, in general, one of two techniques. With the intussusception technique, an opening in the side of an epididymal tubule is made and then the open tubule is pulled inside the end of the vas deferens and sutured in place with 10–0 nylon sutures ([Chan et al., 2005](#)). The open technique, the mucosa of the opening in the side of the epididymal tubule is anastomosed to the mucosa of the vas deferens to complete the end to side anastomosis ([Shekarriz and Pomer, 1991](#)). This technique should only be performed by surgeons with the requisite microsurgery training and high procedural volumes, as good results are dependent on experience and training.

Given that there is a known failure rate for vasectomy reversals regardless of technique used, an option of sperm banking of any intraoperative sperm that are discovered should be discussed with the patient. This further opens up options for in-vitro fertilization in the case that sperm does not return in the ejaculate.

Fig. 1 Illustration of a microscopic 2-layer vasovasostomy. (A) The placement of 6, 10–0 nylon sutures circumferentially through the inner mucosal layer. (B) The placement of multiple 9–0 nylon sutures through the muscularis layer of the vas, forming the second layer. (C) The completed anastomosis. (D) A cross-sectional view of the completed anastomotic sutures.

Table 2 Reported patency and pregnancy rates based on gross appearance of vasal fluid (Belker et al., 1991)

<i>Vasal fluid gross appearance</i>	<i>Patency rate</i>	<i>Pregnancy rate</i>
Watery	91%	49%
Thin, opalescent	93%	59%
Creamy, thick	70%	45%
No fluid	88%	54%

Complications

The complication rates in vasectomy reversal are uncommon, with the most common complication being bleeding from the surgical site, causing a buildup of clotted blood within the scrotum, also known as a scrotal hematoma (Practice Committee of American Society For Reproductive Medicine, 2008). This complication is of particular concern as this may cause pressure on the fragile connection and also release substances in the tissue that may compromise healing and promote scarring. The management of post-operative hematomas after vasectomy reversal varies, with some centers managing this with observation alone, and other centers evacuating and draining these should they arise. The risk of scrotal hematomas is minimized through careful dissection of the tissues and meticulous sealing of any visualized bleeding vessels with electrical current.

With the use of antibiotics prior to the start of the procedure, wound infections are fairly rare. However, should they arise, they should be treated aggressively to prevent compromise of the fragile reversal.

Compromise of the testicular blood supply is also a rare but serious complication of vasectomy reversal. The blood vessels supplying the testicle are usually avoided in the procedure, but should any doubt arise, the presence of the testicular artery can be verified by using a Doppler ultrasound probe in complex cases.

Sperm granulomas can arise postoperatively, indicating that some vasal fluid has leaked out of the anastomosis and caused an inflammatory response. This unfortunately predicts for eventual obstruction of the reversal. The risks of this can be minimized by emphasizing meticulous technique, with accurate realignment of healthy ends of the vas with good blood supply.

Postoperative Care

At the completion of the procedure, fluff gauze and scrotal support are used overlying the dressings. All cases are performed with a single dose of perioperative antibiotics. Patients are counseled to apply an ice pack intermittently for the first few days for comfort and to decrease swelling in the area. They are discharged home with acetaminophen with codeine for analgesia. They are instructed to avoid sexual and strenuous activity for 3–4 weeks. We then see them at 6 weeks for a postoperative visit and to organize a semen analysis to check for patency. If no sperm has returned in the ejaculate by 6 months, then a repeat VV or VE should be considered.

Vasoepididymostomy

Ryan Flannigan and Marc Goldstein, Center for Male Reproduction & Microsurgery, New York, NY, United States

Introduction

Vasoepididymostomy is considered to be the most challenging microsurgical procedure in male reproduction. It is the reconstructive means to anastomose the vas deferens to an epididymal tubule. This technique is used in obstructive azoospermia, where obstruction occurs at the level of the epididymis. The earliest forms of vasoepididymostomy described in 1903, involved opening several epididymal tubules and the vas deferens, and hoping the lumina would fistulize. In 1918, Lespinasse attempted the first deliberate anastomosis of the epididymal and vas deferens (Chan et al., 2003). Due to the microscopic size of the vas deferens lumen (300–500 μm) and the epididymal tubule (150–250 μm), success was limited until the introduction of optical magnification for the procedure by Silber (1978). Since, several variations in technique have been trialed. We will discuss the most contemporary and successful techniques in this article.

Diagnosing Epididymal Obstructive Azoospermia

Etiology

Epididymal obstruction may be congenital or acquired. Congenital forms of epididymal obstruction include hypoplasia associated with cystic fibrosis transmembrane regulatory protein (CFTR) and unilateral or bilateral absence of the vas deferens (CBAVD). Acquired causes of epididymal obstruction include: infectious etiologies, that is, epididymitis, scrotal, or pelvic trauma, vasal obstruction with epididymal blowout, or direct epididymal injury (Wosnitzer et al., 2014). The latter two etiologies are often iatrogenic. The most common being hydrocelectomy, spermatocelectomy, inguina hernia repair, vasectomy, percutaneous epididymal sperm aspiration (PESA), microsurgical epididymal sperm aspiration (MESA) (Fuchs and Burt, 2002).

History and Physical Exam

A thorough history and physical examination are crucial for identification and localization of epididymal or vasal obstruction. A focused reproductive history of both the male and their partner is essential. The clinician should determine if this is primary or secondary infertility, and if either partner has contributed to a pregnancy or been surprised in the absence of a pregnancy with unprotected intercourse. Features on history which may suggest epididymal obstruction include: sexually transmitted infection or epididymitis, scrotal surgery, that is, vasectomy and number of years since vasectomy, orchidopexy, spermatocelectomy, hydrocelectomy, previous attempts at epididymal or vasal reconstruction, inguinal surgery, that is, inguinal hernia repair (especially with mesh), varicocelectomy, excision of lipoma. Furthermore, one should enquire about scrotal or pelvic trauma, or additional pelvic surgeries which may compromise the intraabdominal portion of the vas deferens such as radical prostatectomy, or renal transplant.

On physical examination, the clinician should perform a full reproductive exam including degree of virilization, midline defects, abdominal, and genital assessment. Special attention should be drawn to identifying surgical scars to the abdomen, inguinal region, and scrotum. With a warm, relaxed scrotum, testicles should be palpated for size, firmness, and asymmetries. Epididymal fullness or induration is often present with obstructive azoospermia. Cord structures should be assessed for presence of the vas deferens, vasal defects, and sperm granuloma if previous vasectomy, varicocele, spermatocele, lipoma, and inguinal hernia.

Investigations

Among men with two azoospermic semen analyses, obstructive etiology may be identified by history and physical exam. Low volume semen analyses or ejaculates with a pH of <7.2 should lead one to suspect congenital absence of the vas deferens, or in the presence of palpable vasa, partial absence or ejaculatory duct obstruction (EDO) and a transrectal ultrasound should be performed for diagnosis. EDO is discussed at further depth elsewhere in this text.

Investigations beyond the semen analysis serve to determine if the man has active spermatogenesis. Hormone profiles may identify men with low testosterone, which could be due to hypogonadotrophic hypogonadism (low T, FSH, and LH), or hypergonadotrophic hypogonadism (low T, high FSH >7.6 mIU/mL, and LH). Serum FSH and testicular size are important predictors for differentiating OA from NOA; in one study, a FSH of <7.6 mIU/mL and testicular long axis of >4.6 cm predicts OA in 96% of cases (Schoor et al., 2002). Genetic evaluation for the patient with azoospermia and primary infertility includes a karyotype, γ -microdeletion, and CFTR gene assessment if one or both vas deferens are nonpalpable, or ejaculatory duct obstruction is suspected. In patients with primary infertility, spermatogenesis must be confirmed prior to reconstruction of the excurrent ductal system. A serum anti-sperm antibody assay may be ordered including IgG, IgA, and IgM to assess for active spermatogenesis. The area under the curve (AUC) for ROC curves were 0.92, 0.85, and 0.67 respectively. This translates to a sensitivity and specificity of 85% and 97% respectively for IgG, while the specificity, positive predictive value and positive likelihood ratio for IgA were 99%, 99%, and 70% respectively (Lee et al., 2009). If there are no antisperm antibodies, or if the FSH is abnormally high >7.6 mIU/mL, then confirmation of

obstruction is warranted prior to reconstruction. This may be performed in advance of a planned surgical procedure, or, it may be performed at the beginning of a case with intraoperative microscopic inspection of the epididymis. If markedly dilated tubules are seen, obstruction is confirmed. If the epididymal tubules are flat, a testis biopsy is necessary, with intraoperative microscopic examination of the testicular tissue for presence of sperm. In this case, the patient must be counseled and consented for the different potential procedures depending on the findings. For instance, microscopic testicular extraction of sperm is required if there is abnormal sperm production on the diagnostic biopsy, or reconstruction is required if obstruction is confirmed. Men with secondary infertility due to vasectomy, and proven fecundity, do not need additional confirmation of spermatogenesis if physical exam reveals normal testis volume and consistency and a hormone profile reveals normal serum FSH. A positive serum antisperm antibody assay also suffices to confirm obstruction.

Localizing the Obstruction

Once OA is diagnosed, identifying the level of obstruction requires assessment of history, physical exam, and semen analyses as discussed earlier. EDO is suspected with low semen volume, pH <7.2 and absence of fructose in the semen. TRUS should be performed to assess for seminal vesicle dilation and midline cysts. In the absence of EDO, the level of obstruction is limited to the vas deferens or epididymis. Features on history may identify seminal vesicle side vasal obstruction associated with inguinal surgeries such as hernia repairs, or pelvic surgery such as renal transplant or prostatectomy. Definitive determination of the level of obstruction is imperative to ensure optimal result. This must be determined intraoperatively. First, the surgeon should visualize the epididymis for signs of dilated epididymal tubules and a transition of dilated to nondilated tubules. The transition signifies epididymal obstruction is probable. Next, the surgeon performs a vasotomy and samples fluid from the testicular side of the vas. Presence of abundant sperm or sperm parts confirms patency of the epididymis. Next, a vasogram toward the seminal vesicle side and testicular vasal fluid sampling. The vasogram initially consists of injecting normal saline or lactated ringer's solution through a 24-gauge angiocatheter. Lack of resistance and absence of reflux suggest patency. If resistance or reflux is met, the surgeon may place a 2-0 monofilament suture tail in the vasal lumen on the seminal vesicle side to determine where the suspected obstruction is present. This is diagnostic if it stops in the middle of the hernia scar. A formal vasogram with radio-opaque contrast and intraoperative X-ray may be performed if there is uncertainty regarding the location of the distal obstruction. The surgeon must also sample fluid from the testicular lumen to determine if sperm are present at the level of the vasotomy, indicating lack of epididymal obstruction. Visual appearance of the fluid provides insight to the presence of patency or obstruction; however, microscopic analysis is most definitive. Clear copious fluid suggests an unobstructed epididymis, while thick, toothpaste-like fluid, devoid of sperm, is suggestive of obstruction. Creamy yellow fluid may possess sperm parts and suggest epididymal patency. The fluid is then placed on a glass microscope slide and examined under 400× magnification using bright-field microscopy intraoperatively. The presence of sperm or sperm parts indicates epididymal patency. If no sperm or only rare sperm heads are present, the surgeon must sequentially sample fluid from the epididymis in a stepwise fashion, using a 10-0 needle until sperm or abundant sperm parts are identified. In our experience, we sample every 3-5 mm to identify the most distal site of vasal or epididymal patency, since more distal reconstructions portend to better postoperative patency rates.

Managing Epididymal Obstruction

Once epididymal obstruction has been identified, two management options exist: sperm retrieval for assisted reproductive techniques (ART) or reconstruction in the form of vasoepididymostomy (VE). The former may occur percutaneously via percutaneous epididymal sperm aspiration (PESA) or microsurgical epididymal sperm aspiration (MESA), [Fig. 1](#). Here, couples must be counseled and be willing to undergo ART to obtain pregnancy. PESA may be performed under local anesthetic, using a 21-26-gauge needle inserted percutaneously into the epididymis while withdrawing on the syringe and thus, aspirating sperm. A small volume of fluid (~0.1 mL) is retrieved, and yields thousands to millions of sperm among 61%-96% of men. MESA requires a general anesthetic. Here, the testis is delivered, and under 20-25× magnification with use of an operating microscope, the caput of the epididymis is reflected from the testis, exposing the 7-11 efferent ducts; an efferent duct is selected and punctured. A micropipette is then used to collect the epididymal fluid through capillary action. Sperm is successfully retrieved in 96%-100% of cases yielding 15-95 million sperm. Reconstructive options for epididymal obstruction is a viable option for a skilled microsurgeon and consists of a VE.

Cost-Effectiveness

Men with epididymal obstruction have the choice of sperm retrieval and subsequent in vitro fertilization/intracytoplasmic sperm injection (IVF/ICSI) or VE. The latter appears to be more cost-effective with an estimated cost per live delivery, in 1997 dollars, of \$31,099 based upon an 85% VE patency rate and 36% live birth rate. Meanwhile, sperm retrieval via MESA and subsequent IVF/ICSI had a cost per live delivery rate of \$51,024. This particular study considered both direct and indirect costs to the associated procedures ([Kolettis and Thomas, 1997](#)). Several other studies have supported vasal reconstruction for men with previous vasectomies as being more cost effective compared to sperm retrieval and IVF/ICSI; however, these series include vasovasostomies which characteristically have higher patency rates compared to VE's.

Fig. 1 (A) Percutaneous epididymal sperm aspiration (PESA). Under local anesthetic (skin and cord block), a 21–26 gauge needle is inserted to the epididymis, and epididymal fluid is aspirated for the presence of sperm. (B) Microsurgical epididymal sperm aspiration (MESA). Under general anesthetic, the testis is delivered and the tunica vaginalis is opened exposing the epididymis. The caput of the epididymis is reflected gently by incising the tunica albuginea at the junction of the testis and caput. The efferent ducts are visualized, and one is punctured. A micropipette is used to aspirate the sperm containing fluid by capillary action.

Vaso-Epididymostomy Surgical Principles

Surgical Incision and Mobilization

Vertical hemiscrotal incisions should be made in the mid to upper scrotum, this affords the ability to extend the incision cranially if additional dissection of the abdominal vas deferens is necessary. The testis is delivered with the tunica vaginalis intact. The vas deferens is then identified and separated from the rest of the spermatic cord with a Penrose drain at the site of previous vasectomy or at the junction of the straight and convoluted vas if the patient has not previously undergone vasectomy. The operating microscope is then used to carefully dissect the peri-vasal vessels off of the vasal surface at the site of planned vasotomy.

Identifying the Site of Obstruction

A hemivasotomy is performed and the vasal fluid is assessed visually, and smeared onto a glass slide and examined under $400\times$ bright-field microscope for the presence of spermatozoa. **Table 1** provides an overview of vasal fluid findings and procedure necessary. If thick white toothpaste-like fluid with no sperm is found in the case of a previous vasectomy, then a VE is indicated. Here, the epididymal tubules must be carefully evaluated starting at caudal end of the epididymis. A tubule is then punctured and the fluid is examined under the bright-field microscope. This is repeated moving 2–3 mm proximally until sperm is identified. If the line of demarcation is clearly seen with dilated tubules above and collapses below, one can go straight to set up for a vasoepididymostomy.

Preparing for the Anastomosis

Once a dilated tubule above the obstruction is identified, the site of anastomosis is prepared by excising a 2.5 mm ellipse of tunica overlying the favorable, dilated tubules. The abdominal vas deferens must have adequate length for a tension free anastomosis. The posterior vasal sheath is then sutured to the cranial portion of the tunical window to prevent tension during the anastomosis.

Table 1 Intraoperative testicular end vasal fluid is sampled at the time of vasal reconstruction for OA

<i>Vasal fluid</i>	<i>Microscopic findings</i>	<i>Surgical procedure indicated</i>
Copious clear fluid	No sperm	Vasovasostomy
Cloudy fluid	Intact sperm	Vasovasostomy
Creamy yellow fluid	Sperm heads	Vasovasostomy
Thick white toothpaste-like fluid	No sperm	Vasoepididymostomy
Dry vas with no granuloma	No sperm	Vasoepididymostomy
Dry vas with granuloma at vasectomy site	Barbotage fluid reveals sperm	Vasovasostomy

The decision to proceed with vasovasostomy compared to vasoepididymostomy is made by examining the appearance of the vasal fluid and the microscopic findings.

Unique Considerations

Obstruction of Both Epididymis and Abdominal Vas Deferens

In this scenario, the vasal fluid from the hemi-vasotomy demonstrates an absence of spermatozoa and injection of normal saline is met with resistance to the abdominal vas deferens. The tail of a 2–0 monofilament suture may be used to cannulate the abdominal vas and locate the site of obstruction; if localization is unclear, a formal vasogram should be performed to determine the site of obstruction. If the obstruction is at the level of the inguinal canal, we recommend sperm retrieval if the couple is willing to undergo IVF/ICSI, closing the hemi-vasotomy, and abandoning the VE. If the hemi-vasotomy is small and vessels preserved, then inguinal vasovasostomy may be considered during the initial procedure with plans for a delayed scrotal VE in 6 months. This period of time will allow the inguinal vasovasostomy site to heal and reconstitute vascularization to the intervening vas deferens. Performing both a scrotal VE and an inguinal VV would result in devascularization of the intervening segment of vas deferens. In a second scenario, with the site of distal obstruction localizing to the ejaculatory ducts, we recommend management of the EDO first, and if successful, subsequent VE.

Crossed Vasoepididymostomy

Men that have a clear asymmetry in testis quality, that is, atrophic or absent unilateral testis, accompanied with a contralateral vasal obstruction, that is, inguinal hernia repair, renal transplant, then a crossed vasal reconstruction may be considered. Here, the better quality testis is confirmed to be obstructed, while the poor quality testis has a patent abdominal end of the vas deferens as confirmed intraoperatively. The optimal procedure to facilitate sperm returning to the ejaculate is to anastomose the testicular end of the vas deferens or epididymis (based upon microscopic analysis of vasal fluid results) of the best quality testis to the patent vas deferens from the side of the atrophic testis. Here, the testicular vas deferens is tunneled through a copious opening in the scrotal septum for a tension free anastomosis; if vasal length for is a concern, the better testis can be transposed to the contralateral side.

Varicocele and Vasoepididymostomy

In the event that a patient presents with both epididymal obstruction and a varicocele, it is recommended to treat the epididymal obstruction first. By correcting the obstruction, the patient has the opportunity to develop sperm in the ejaculate and obtain paternity without requiring a varicocele repair (VR). However, if pregnancy is still not achieved due to presumed implications from the varicocele, we recommend waiting 6 months to perform the VR. We advocate against performing simultaneous VE and VR due to the venous congestion at the site of anastomosis. This congestion is unlikely to aid in healing the delicate anastomosis.

Vasoepididymostomy Surgical Techniques

Several techniques for VE are discussed in this section. End-to-end and end-to-side techniques were among the first described. More contemporary techniques include intussuscepting the epididymal tubule into the vasal lumen using two or three sutures. In a randomized controlled trial using an animal model, Chan and colleagues determined the highest patency rate among the longitudinal intussuscepted vasoepididymostomy (LIVE) two suture technique. Regardless of technique, the microsurgeon must practice strong principles of surgery for optimal results. These include, tension free and water-tight anastomosis, atraumatic tissue handling, precision of needle placement, square knots, a bloodless operating field, and preservation of anatomy while optimizing necessary exposure.

End-to-End Technique

An end-to-end (EE) anastomosis to a specific tubule is the original technique for VE as described by Silber (1978). The epididymis is cut in cross-section starting caudal and moving toward the caput systematically. Bipolar cautery is used to control bleeding vessels, and the epididymal fluid is assessed under a microscope for the presence of sperm. If no sperm is identified, a more proximal section is made. If sperm is found, the epididymis is milked until only one tubule continues to ooze clear fluid, this fluid is sampled once more to ensure sperm is present prior to the anastomosis. The epididymal tubule is then anastomosed to the vasal lumen with four to six, 9–0 or 10–0 sutures placed inside-out on the epididymal tubule to the corresponding location on the vas deferens, Fig. 2. A second, muscular layer anastomosis is performed to achieve a watertight anastomosis.

End-to-Side Technique

Most contemporary techniques beyond the conventional end-to-side (ES) use this approach. However, in the conventional ES technique, no intussusception is performed. Here, an epididymal tubule with sperm is identified as mentioned in section “Identifying the Site of Obstruction.” The selected epididymal tubule is then punctured with a microknife or microscissors and the fluid is tested again to confirm sperm. Methylene blue may be used to differentiate the out and inner surface of the epididymal tubule. Three to six double-armed 10–0 sutures are then placed inside-out in the epididymal tubule, then to the corresponding location in an inside-out fashion, Fig. 3. A second anastomotic layer is performed with 9–0 sutures from the muscularis of the vas deferens to the cut tunical edge on the epididymis.

Fig. 2 End-to-end vasoepididymostomy. Here, the epididymal tubule that contains to leak fluid is likely the patent tubule containing sperm. This fluid may be tested under a microscope for presence of sperm. Four to six 9–0 or 10–0 sutures have been used for this anastomosis. A second layer of 9–0 sutures are then placed peripherally.

Fig. 3 End-to-side vasoepididymostomy. Here, the epididymal tubule that is dilated and contains sperm is opened with a 15° microknife or microscissors (A). Three to six 9–0 or 10–0 sutures are then used for the lumen anastomosis (B). A second layer of 9–0 sutures are then placed peripherally.

Fig. 4 Intussuscepted three-suture triangulation. Here, the dilated epididymal tubule containing sperm is isolated. Three double-armed 10-0 sutures are placed and partially pulled through the tubule in a triangulating orientation. A 15° microknife is then used to incise the lumen between the sutures. The needles are then pulled through and placed to the corresponding locations of the vas deferens inside to out. Upon tying these sutures, the epididymal tubule is intussuscepted into the vasal lumen. A second layer of 9-0 sutures are then placed from the outer edge of the vas deferens to the tunica of the epididymis circumferentially.

Fig. 5 Intussuscepted two-suture transverse technique. Here, the dilated epididymal tubule containing sperm is isolated. Two double-armed 10-0 sutures are placed and partially pulled through the tubule in a transverse orientation. A 15° microknife is then used to incise the lumen between the sutures. The needles are then pulled through and placed to the corresponding locations of the vas deferens inside to out. A 9-0 suture is then placed opposite to the original approximating 9-0 suture and tied. This opposes the vasal lumen and the epididymal opening, allowing for avoidance of tension to the epididymal anastomosis. Upon tying these sutures, the epididymal tubule is intussuscepted into the vasal lumen. A second layer of 9-0 sutures are then placed from the outer edge of the vas deferens to the tunica of the epididymis circumferentially.

Intussuscepted Three-Suture Triangulation Technique

The intussuscepted three-suture technique was the first technique to utilize intussusception and was first described by [Berger \(1998\)](#). This technique uses the same approach to isolate the epididymal tubule of choice as the above ES technique. This anastomosis however, differs from the conventional ES technique. Here, three double-armed 10-0 suture needles are placed partially through the epididymal tubule in a triangular fashion, prior to incising the tubule. Since the needles are larger diameter than the suture connected to the needle, leaving the needle in the tubule allows the tubule to maintain fullness for more precise placement of the 2nd and 3rd sutures, [Fig. 4](#). Following placement of all three sutures, the tubule is incised with a 15° microknife, and the sutures are then placed inside-out to the vasal lumen, intussuscepting the opening of the tubule into the vasal lumen. The sutures are gently placed on traction until the tail of the suture begins to move, and are then tied. A second layer of 9-0 sutures are placed from the muscularis of the vas deferens to the tunical edge for a watertight closure.

Intussuscepted Two-Suture Transverse Technique

Marmar first described the two-suture transverse intussusception technique ([Marmar, 2000](#)). This technique involves the same preparation as the three-suture intussusception technique; however, two doubled-armed 10-0 sutures are placed perpendicular to the length of the epididymal tubule, and kept only partially drawn through, [Fig. 5](#). A 15° microknife is then used to make a transverse incision between the two needles. The ends of the 10-0 sutures are then placed inside out to the corresponding locations in the vas

Fig. 6 Longitudinal intussuscepted vasoepididymostomy (LIVE). Here, the dilated epididymal tubule containing sperm is isolated. A 9-0 suture is placed on the posterior side of the vas deferens and tied to the corresponding side of the epididymal tunica to bring the vas in close approximation and avoid any tension. Four microdots are placed at the junction of the mucosa to muscularis of the vas deferens to plan the vasal stitches. Two double-armed 10-0 sutures are placed and partially pulled through the tubule in a longitudinal orientation. A 15° microknife is then used to incise the lumen between the sutures. The needles are then pulled through and placed to the corresponding locations of the vas deferens inside out. A 9-0 suture is then placed opposite to the original approximating 9-0 suture and tied. This opposes the vasal lumen and the epididymal opening, allowing for avoidance of tension to the epididymal anastomosis. Upon tying these sutures, the epididymal tubule is intussuscepted into the vasal lumen. A second layer of 9-0 sutures are then placed from the outer edge of the vas deferens to the tunica of the epididymis circumferentially.

Fig. 7 Single arm suture longitudinal intussuscepted vasoepididymostomy (LIVE). Here, the dilated epididymal tubule containing sperm is isolated. A 9-0 suture is placed on the posterior side of the vas deferens and tied to the corresponding side of the epididymal tunica to bring the vas in close approximation and avoid any tension. Four microdots are placed at the junction of the mucosa to muscularis of the vas deferens to plan the vasal stitches. Two single arm sutures are placed outside-in from the microdots out through the lumen. The needles are then placed in a direction back toward the vas deferens in the epididymal tubule in a longitudinal fashion and partially pulled through the tubule. A 15° microknife is then used to incise the lumen between the sutures. The needles are then pulled through and placed to the corresponding locations of the vas deferens inside to out. A 9-0 suture is then placed opposite to the original approximating 9-0 suture and tied. This opposes the vasal lumen and the epididymal opening, allowing for avoidance of tension to the epididymal anastomosis. Upon tying these sutures, the epididymal tubule is intussuscepted into the vasal lumen. A second layer of 9-0 sutures are then placed from the outer edge of the vas deferens to the tunica of the epididymis circumferentially.

deferens. A second layer of interrupted 9-0 sutures are placed from the muscularis of the vas deferens to the tunical edge as with the three suture technique.

Intussuscepted Two-Suture Longitudinal Technique

Preferred technique, Chan, Li, and Goldstein described the double-armed longitudinal intussuscepted vasoepididymostomy (LIVE) technique and is the authors preferred technique ([Chan et al., 2003](#)). It involves the same preparation as the above two and three suture techniques. At our institution, we emphasize the importance of a consistent setup. Using a microtip surgical marker, we place four microdots at the transition of mucosa to muscularis of the vas deferens to separate planning from execution of needle

placement. In the LIVE technique, use of double-armed and single-armed sutures has been described. In the standard double-arm technique, two double-armed 10-0 sutures are placed longitudinally in the epididymal tubule, but not pulled through (Fig. 6). The needle is 70 μm in diameter, but the suture is only 17 μm , so if the needles are pulled through before both are placed, and the tubules incised, sperm will leak from the suture holes and the tubule will collapse, obviating a major benefit of the intussusception technique. A longitudinal incision between the sutures is then made with a 15-blade microknife and the suture ends are carefully pulled through the epididymal tubule and placed in the respective positions in the vas deferens inside-to-out through the microdots. However, in the single-arm technique, the 10-0 suture must first be placed outside-to-in, through the microdot, and out of the lumen, Fig. 6. The needles are then placed longitudinally in the epididymal tubule, and partially withdrawn. The tubule is opened as in the double-arm technique, then the single arm sutures are placed to the corresponding locations on the vas deferens inside-to-out. The single arm technique may be used where double-armed sutures are not available, Fig. 7. Prior to tying the 10-0 sutures, one end is pulled until the other end begins to move; at this point, it may be assumed that the slack has been removed and an appropriately intussuscepted anastomosis has been created. The second layer of 9-0's are then placed in an interrupted fashion as above to prevent leakage and subsequent sperm granuloma which may cause a late failure. We prefer the LIVE technique to the two-suture transverse technique since there is less risk of inadvertently transecting the epididymal tubule. Furthermore, Chan et al. performed a randomized trial in an animal model that demonstrated best patency rate among the LIVE technique (Chan et al., 2003).

Outcomes and Complications

For the LIVE technique, patency results have varied (48%–84%), but the highest reported rate was 84% at Weill Cornell, with a paternity rate of 40%, 31% of which required in vitro fertilization or intracytoplasmic sperm injection using fresh ejaculated sperm (Chan et al., 2005). Semen analyses may be ordered at 1 month postoperatively then every 3 months thereafter. Up to 60% of men will have sperm return to the ejaculate within 1-month post operatively. Mean sperm counts following LIVE are 12.8 (0.01–80) million with 21% motility (0%–30%) (Chan et al., 2005). Patients may develop a late failure where motile sperm was initially present, and they later become azoospermic. This has been estimated to occur at a rate of 8%–30% (Schiff et al., 2005). Thus, it is important to consider cryopreservation of ejaculated motile sperm postoperatively at first presentation in the event of an unfortunate late failure. Other potential complications include: scrotal hematoma, failure of anastomosis, wound infection, epididymorchitis, orchalgia or more rarely testicular atrophy or fibrosis of the epididymis. These complications are not common but should always be discussed with the patient prior to surgery at the time of informed consent. Diligent surgical technique can mitigate many of these complications, and never hesitate to place a Penrose for 24–48 h to prevent scrotal hematoma. Other important considerations are to maintain patient body temperature throughout the case and ensure the patient is well padded and positioned to avoid a position injury. These may occur with the arms outstretched for a long period of time, as such anesthesia should massage the arms and shoulders or safely reposition the arms between sides for a short break during the case.

Summary

Vasoepididymostomy is both cost effective compared to immediate in vitro fertilization and an effective surgical procedure to relieve epididymal obstruction in men wishing to achieve paternity. The LIVE technique has been well adopted internationally, with success using both single and double-armed sutures. A high regard for surgical principles are necessary for optimal results when performing vasoepididymostomies.

Non-Microsurgical Testis Sperm Extraction

Paul J Turek, The Turek Clinic, San Francisco, CA, United States

Introduction

Azoospermia is the absence of spermatozoa in the semen on two centrifuged semen samples. It affects 1% of the general population and up to 15% of infertile men (Jarow et al., 1989). Azoospermia takes two forms: obstructive conditions due to blockages within the reproductive tract, and nonobstructive disorders generally due to testicular failure. With the advent of in vitro fertilization (IVF) in 1978 and intracytoplasmic sperm injection (ICSI) in 1992, the opportunity for men with both types of azoospermia to conceive has increased dramatically (Palermo et al., 1992).

A Cochrane meta-analysis suggests that there is currently insufficient evidence to recommend a specific sperm retrieval technique over another for either obstructive or nonobstructive azoospermia (Van Peperstraten et al., 2006). In other words, based on our current knowledge, there is no “best” way to get sperm from the testicle. This has opened the door to the development of a variety of techniques, including minimally invasive procedures, to optimize both the safety and success of sperm retrieval. The biggest “safety” issue with sperm retrieval procedures is surgically-induced low testosterone or hypogonadism. During testicular sperm retrieval procedures, hormone producing Leydig cells are removed along with sperm producing cells. In addition, collateral damage to nearby testicular tissue from bleeding and devascularization during procedures can also induce hypogonadism. This is especially true in cases of nonobstructive azoospermia, in which men may be borderline hypogonadal at baseline, and large, invasive sperm retrieval procedures can result in the need for lifelong testosterone replacement. In addition, as multiple IVF-ICSI cycles may be needed for pregnancy or family building success, clinicians should develop *efficient* sperm retrieval techniques that *maximize* yield and *minimize* procedure extent and morbidity (Turek et al., 1999). With these concepts in mind, we review various testicular sperm retrieval procedures currently employed in azoospermic men.

Testis Sperm Retrieval With Azoospermia

The first use of testicular sperm with ICSI represented a great leap forward for the field, as it demonstrated that sperm do not require epididymal maturation to fertilize oocytes. Testicular sperm extraction is now used routinely in obstructive azoospermia and is essential for nonobstructive azoospermia (NOA).

Testis Sperm Retrieval With Obstructive Azoospermia

Testicular sperm in obstructed patients can be retrieved by needle aspiration (testicular sperm aspiration or TESA), by percutaneous biopsy or by open surgical biopsy (testicular sperm extraction or TESE). TESA is performed on an outpatient basis under local anesthesia with or without IV sedation (Fig. 1). It may be timed to occur with oocyte harvest, or it can be done in advance with cryopreservation. The technique involves stabilization of the testicle in the scrotal sac between the thumb, index, and middle fingers after local spermatic cord block is given. Next, a butterfly or angiocatheter needle is directed percutaneously into the testicular parenchyma through the skin (Marmar and Benoff, 2005). If an angiocatheter needle is used, the hollow needle is withdrawn, leaving the soft plastic catheter sheath within the testicle. Negative pressure is applied either directly with a syringe connected to the angiocatheter or by using arterial tubing attached to the catheter on one end and to the syringe on the other. The catheter or needle is passed back and forth within the substance of the testicle while maintaining the vacuum seal. When sufficient tissue is collected, the suction is released and the needle or catheter removed from the testicle. Using air or wash medium, aspirated tissue is flushed into a Petri dish or collection tube containing media. After fine dissection with scissors or scalpels, the tissue-fluid is examined with microscopy to confirm sperm presence. Repeat sperm aspiration can be performed on the same or opposite testicle as needed (Donoso et al., 2007). Pressure applied to the aspiration site is sufficient for hemostasis. The recovery period is 24 h. Complications include bleeding (1%) and infection (1%).

An alternative to TESA for testicular sperm retrieval involves percutaneous or open surgical biopsy, termed testicular sperm extraction (TESE). The timing of TESE is similar to TESA and is either coincident with oocyte harvest or performed in advance with sperm cryopreservation. The percutaneous TESE technique involves stabilization of the testicle as described with TESA. However, instead of using a butterfly needle, a biopsy gun loaded with a 14-gauge needle is used to obtain core biopsies of the testicle (Tuuri et al., 1998). Aided by a skin puncture by scalpel, the biopsy needle is advanced through the skin and into the testicular tunica albuginea either at the lower or upper pole of the testicle and is directed parallel to the long axis of the testicle. After firing the biopsy gun, the excised tissue core is placed in culture medium for processing. The main risk with testis tissue retrieval by biopsy gun is hematoma, which occurs in 1%–5% of cases as assessed by ultrasound (Tuuri et al., 1998).

Open surgical testicle biopsy (TESE) is a third option for obstructive azoospermia (Fig. 2). This is generally performed through a “window technique” in which the testicle and scrotum are stabilized and the scrotal skin incised with 1 cm incision (Coburn and Wheeler, 1991). The tunica vaginalis is opened and the tunica albuginea of the testicle incised parallel to the visible surface vessels. Testicular tissue is excised and processed for IVF-ICSI similar to TESA samples. The tunica albuginea and scrotum are closed with

Fig. 1 Testis sperm aspiration (TESA) is performed by needle biopsy. Adapted with permission from Smith J and Turek PJ. Reproductive medicine. Netter's Images. 2nd edn, Vol 1. Elsevier Press, Philadelphia. 2011.

Fig. 2 Testis sperm extraction (TESE) is performed by incisional biopsy. Adapted with permission from Smith J and Turek PJ. Reproductive medicine. Netter's Images. 2nd edn, Vol 1. Elsevier Press, Philadelphia. 2011.

absorbable sutures. The recovery period is 24–48 h and procedural risks are low but include infection (<1%), bruising and bleeding (<5%).

In studies that have examined intratesticular bleeding after testis sperm retrieval, a risk factor for hypogonadism, the risk appears to be higher with open (29%) compared to percutaneous (7%) biopsy techniques ([Harrington et al., 1996](#)). A more worrisome adverse effect from testicular sperm extraction is reduction in testosterone production after large or repeated procedures.

Testis Sperm Retrieval With Nonobstructive Azoospermia

Nonobstructive azoospermia (NOA) underlies most cases of azoospermia. The physical examination typically reveals testicular atrophy and the hormonal analysis demonstrates elevated follicle stimulating hormone (FSH) levels. Unlike the findings from

Fig. 3 Demonstration of the focal or “patchy” nature of sperm production in the NOA testis. This figure was derived from fine needle aspiration “mapping” of the testis. Numbers indicate mapped sites within the testis. Circles and lines show where sperm were found at a density of 1 sperm/hpf on cytological smear. Numbered areas without circles showed Sertoli cell-only on cytological review.

obstructive azoospermia, only about half of NOA cases will have mature testicular sperm for ICSI (Kahraman et al., 1996; Tournaye et al., 1997). Furthermore, clinical parameters such as testicular size, hormone levels, and testis biopsy patterns do not accurately predict whether a testicular procedure will yield sperm (Tournaye et al., 1996; Mulhall et al., 1997).

It is also well known that sperm production in NOA testes may be “focal” or “patchy” in nature (Turek et al., 2000) (Fig. 3). This makes testicular sperm aspiration (TESA) less effective than TESE procedures for successful sperm retrieval. Despite the opportunity to sample more testis tissue with TESE vs. TESA procedures, they can still fail to find sperm if performed in blind or random fashion. To address the problem of focal sperm production in NOA, several strategies have been developed to find sperm while minimizing testicular damage.

Multibiopsy testicular sperm extraction (TESE)

The multibiopsy TESE technique was developed in 1997 to maximize successful sperm retrieval by increasing sample size to increase the likelihood of finding sperm. Compared to a single tunical incision in simple TESE procedures, multibiopsy TESE involves several tunical incisions (up to 15) with tissue extraction until sufficient sperm is obtained (Fig. 4). This procedure can be performed in advance of ICSI and all sperm frozen for later use or can be timed to oocyte harvest. The original description of the technique in $n = 21$ patients found sperm in 70% of patients (Mulhall et al., 1997). A more recent study ($n = 741$ patients) examined the optimal number of biopsies needed to find sperm using the multibiopsy approach on a single testicle and found that sperm retrieval rates ranged from 44% for a single biopsy to 58% for four biopsies. Adding a fifth biopsy on the contralateral testis increased overall yield by only 1% (Dadkhah et al., 2013). Other contemporary studies among a total of almost 300 NOA men revealed sperm retrieval rates of 47%–48% using a multibiopsy approach (Schwarzer et al., 2013; Sacca et al., 2016).

Soon after the description of the multibiopsy TESE, in 1998 Schlegel developed microdissection TESE that allowed for improved localization of testis with the aid of intraoperative microscopy (Ostad et al., 1998). This technique will be discussed elsewhere. However, comparison purposes, there is thought to be an increase in sperm retrieval rates of about 11%–18% using microdissection rather than conventional single TESE (Schwarzer et al., 2013; Schlegel, 1999). Two systematic reviews have been published recently that compare sperm retrieval outcomes with conventional TESE and microdissection TESE (Deruyver et al., 2014; Bernie et al., 2015). In the European study, 62 studies were analyzed and sperm retrieval was observed to be higher in the microTESE (43%–63% sperm retrieval rate) than in the conventional TESE group (17%–45% sperm retrieval rate) (Deruyver et al., 2014). However, in patients with uniform maturation arrest biopsy histology, there was no benefit to mTESE vs. TESE procedures. Interestingly, this histology-specific finding mirrors prior reports that found that mTESE lacks superiority to TESE in cases of maturation arrest histology as seminiferous tubules tend to be of uniform size, reducing the ability to optically discriminate sperm-containing tubules (Amer et al., 2000; Takada et al., 2008). In the U.S. paper, a review of 15 studies, mTESE was deemed 1.5-fold more likely to find sperm than conventional TESE (Bernie et al., 2015). It should be noted however, that no randomized, prospective studies have been performed that directly compare the two sperm retrieval techniques.

As described earlier, a significant safety issue in men with non-obstructive azoospermia is hypogonadism after sperm retrieval procedures. It has been reported that if fewer TESE biopsies are taken, there is a less pronounced testosterone decrease (Silber, 2000). However, even with its more precise tissue dissection, microdissection TESE can have measurable effects on androgen balance: among experienced surgeons, serum testosterone levels recover to baseline in only 50%–85% of patients after 1 year (Everaert et al., 2006; Takada et al., 2008; Ishikawa et al., 2009; Dabaja and Schlegel, 2013). Because of the effects of TESE on androgen balance, and the lack of randomized data comparing various sperm retrieval techniques, some have advocated using a “stepwise” multibiopsy approach to finding sperm in which a single TESE sample is taken, followed by a micro-TESE using the same testicular

Fig. 4 Schematic drawing of the incisions made in the testicular tunical albuginea in the multibiopsy TESE (left) and FNA mapping (right) techniques. Permission from Smith J and Turek PJ. Reproductive medicine. Netter's Images. 2nd edn, Vol 1. Elsevier Press, Philadelphia. 2011.

incision, followed by a multibiopsy approach on the opposite testis if needed (Franco et al., 2016). This highlights the need for innovative strategies that can (a) improve sperm localization, and (b) reduce the extent of TESE procedures in NOA men.

Fine needle aspiration mapping and “map-guided” TESE

First published in 1997, fine needle aspiration (FNA) map-guided TESE is a two-step nonmicrosurgical procedure that first localizes and then retrieves sperm in the testes (Turek et al., 1997). First, sperm is identified through nonsurgical FNA testicular “mapping,” and then sperm retrieval follows, and is “guided” by the map findings (Figs. 5 and 6). This results in a high chance of successful sperm retrieval by focusing procedures on precise areas within testicles that are known to have sperm, thereby minimizing procedural invasiveness (Beliveau and Turek, 2011). Liken this concept to using GPS to find the shortest way to travel somewhere before beginning the trip. Performed under local anesthesia, FNA mapping involves taking a templated set of aspirated tissue samples, ranging in number from 4/testicle in a simple map to 18/testicle in a compound map (Fig. 4). Aspirated seminiferous tubules undergo routine Papanicolaou staining and are examined by a cytopathologist for sperm (Ljung, 1992). As it is incisionless, recovery is less than 24 h and an average of two pain pills are taken post-procedure. Reported rates of finding sperm in NOA patients with FNA mapping range from 47% to 68% depending on the population studied (Turek et al., 2000; Shefi et al., 2009; Beliveau and Turek, 2011).

If sperm are found on FNA mapping, the couple is counseled to proceed with sperm retrieval and IVF-ICSI. The method of testis sperm extraction is governed by the findings from the mapping procedure (Fig. 6). In a series ($n = 105$) of mapped NOA cases, 44% of patients needed TESA, 33% required TESE, and 23% used microdissection-TESE to retrieve sufficient sperm for all eggs at ICSI, demonstrating the ability of diagnostic mapping to reduce the need for microdissection-TESE sperm retrievals in NOA men

Fig. 6 Approach to FNA map guided sperm retrieval. Green circles are geographical areas of the testicle with mature sperm. Red lines and circles are planned incisions or aspiration sites. Note how sperm retrieval can be targeted to sperm positive map sites to minimize extent of sperm retrieval procedures. Permission from Smith J and Turek PJ. Reproductive medicine. Netter's Images. 2nd edn, Vol 1. Elsevier Press, Philadelphia. 2011.

Fig. 7 A schematic showing the clinical pathway for sperm retrieval after initial diagnostic FNA Mapping in $n = 96$ patients. Overall success (sufficient sperm retrieved for all eggs at IVF-ICSI) occurs in 95% of men.

(Beliveau and Turek, 2011). In addition, all microdissection cases in this series were unilaterally performed. Overall, sufficient sperm (enough for all eggs at IVF) is obtained at retrieval after FNA mapping in 95% of cases (Fig. 7). Recently, FNA mapping has also been shown to be particularly effective in finding testicular sperm in cases of cryptozoospermia and failed microdissection TESE procedures (Turek et al., 2016a,b). By significantly curtailing the use of microdissection yet maintaining high sperm yields in NOA cases, sperm mapping could theoretically limit post-surgical hypogonadism. Indeed, the safety profile of the FNA approach has been confirmed in both human and animal studies (Dahlbom et al., 1997; Turek et al., 2000; Gouletsou et al., 2010). Recently described variations on the sperm mapping concept include single-site, percutaneous, multipass tissue sampling (Jensen et al., 2016) and single-seminiferous tubule biopsy through open micropuncture (Shah, 2001).

Conclusions

From an evidence-basis, several microsurgical and nonmicrosurgical sperm retrieval techniques exist and no single procedure is considered the "best" from a risk-reward profile for either obstructive or non-obstructive azoospermia. A summary comparison of these techniques is outlined in Fig. 8. Although it is not difficult to retrieve sperm in obstructed cases, it can be very difficult to find sperm in NOA, as sperm production may be "patchy" or "focal." Unfortunately, no prospective, randomized controlled trials guide our sperm retrieval strategies for NOA patients. However, since ICSI is not always successful, it behooves reproductive urologists to develop and apply retrieval techniques that are reliable, of low morbidity, and that harvest sufficient sperm to enable multiple ICSI attempts without repetition.

Fig. 8 A schematic comparison of various sperm retrieval techniques based on information obtained, invasiveness and complications. *Note:* Mapping = FNA mapping; MicroTESE = microdissection TESE.

Key Points

- All men with obstructive azoospermia and a majority of men with nonobstructive azoospermia will have sperm for biological pregnancies.
- There is currently insufficient high-level evidence to recommend any specific sperm retrieval technique over another for either obstructive or nonobstructive azoospermia.
- The onus is on clinicians to develop sperm retrieval techniques that maximize yield and minimize procedure numbers and morbidity.

Microsurgical Testis Sperm Extraction

Tolulope Bakare, University of Illinois, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Assisted reproductive techniques have become an effective means of managing male-factor infertility. The advancement of in vitro fertilization (IVF) using intracytoplasmic sperm injection (ICSI) has led to the development of more sophisticated sperm retrieval techniques which has increased the number of men with male factor infertility who successfully father children. Conventional testicular sperm extraction has been used in management of these patients. This procedure involves the creation of a small window in the testis and random biopsy is obtained and evaluated for sperm. If sperm is found, it is then used in in vitro fertilization. In order to minimize tissue removed during conventional testicular sperm extraction (TESE), and to maximize the amount of sperm collected from the testicle, microsurgical testicular sperm extraction (micro-TESE) was developed. This technique (described below) originally described in 1999 has been proven to enhance the number of sperm extracted in specifically in men with spermatogenic dysfunction when compared to random biopsies (Schlegel, 1999). The technique is also used in extracting sperm when conventional sperm extraction methods have resulted in no sperm. Although, the incision for a micro-TESE is larger than conventional TESE, less intra-testicular reaction including scarring, and calcifications, has been noted on ultrasound in patients who undergo micro-TESE compared to conventional TESE (Ramasamy et al., 2005).

Technique

A midline scrotal incision is made through the raphe with electrocautery, entering into the hemiscrotum. The testicle is delivered within its tunica vaginalis and the tunica vaginalis is entered in a controlled fashion. The testicle is inspected for any gross abnormalities. The testicle may then be packed with moist gauze and the steps may be repeated on the contralateral side. The surgical microscope is then brought and docked into position, to perform the rest of the procedure under surgical magnification. A transverse incision is made through the tunica albuginea, away from any subcutaneous vessels to maintain the integrity of the testicular blood supply. The surgeon's nondominant hand holds the everted testicle while the dominant hand carefully and systematically dissects the extruded seminiferous tubules under high-power magnification (Fig. 1). Selected areas were identified which were notably more prominent and full with regard to tubular size than other areas within the testicle (Fig. 2). These tubules are removed bluntly with forceps and placed in the sperm cryopreservation medium, and sent to the embryologist, who examines the tissue and extracts sperm. Hemostasis is achieved with the judicious use of bipolar electrocautery. The tunica albuginea is closed with a running suture. The procedure is also performed on the contralateral testicle. The tunica vaginalis is closed on either side with a running suture. Each testicle is then returned into the hemiscrotum in the correct orientation, and the wound is closed. A compressive dressing may be applied to the base of the groin.

Post Surgical Care

Post operative instructions include application of ice packs to the surgical site for up to 48 h post operative, no heavy lifting that is, greater than 20 lb for 2–3 weeks post operatively, and no sexual activity for minimum of 48–72 h. Patients may resume sexual activity after that per their discretion. Pain medication is prescribed on a as needed basis. Oral antibiotics may be given for 3–5 days, but a single dose given during surgery may be sufficient (Akalin, 2002).

Fig. 1 Schematic representation of the microdissection TESE procedure.

Fig. 2 Dissected testicular tissue during microsurgical testis sperm extraction with prominent tubules.

Outcomes of Microsurgical Testicular Sperm Extraction

The ability to identify seminiferous tubules containing developing germ cells, which appear larger and more opaque under the microscope, has resulted in increased successful sperm retrievals using this technique. The chances of finding spermatozoa in patients with spermatogenic dysfunction has been shown to increase from 45% to 63% (Schlegel, 2009). Comparative assessments performed also revealed significantly higher sperm retrieval rates with micro-TESE when compared to conventional TESE (47% vs. 30%) (Amer et al., 1999). However, the success of sperm extraction depends on the etiology of male-factor infertility, the skill and experience of the surgeon, and the processing of the specimen after retrieval. When compared to patients with obstructive azoospermia, results of surgical sperm retrieval are lower in patients with nonobstructive azoospermia or spermatogenic dysfunction. This is due to the abundance of sperm in obstructive azoospermia patients. These patients can be treated with a wide variety of techniques and typically do not warrant microsurgical extraction. In contrast, Nonobstructive azoospermia also known as spermatogenic dysfunction is characterized by impairment of the endocrine and/or exocrine functions of the testis that is, impaired spermatogenesis. In a few instances, spermatogenic failure may result from hypogonadism, which may result from hypothalamic, pituitary or testicular disorders. More commonly however, nonobstructive azoospermia results from testicular failure with borderline to low serum testosterone. Medical therapies that increase serum testosterone may also increase intratesticular testosterone. However, it is uncertain if low testosterone in these patients predicts retrieval rates with microsurgical sperm extraction. In patients with Klinefelter's syndrome, men with a low baseline testosterone who were treated and responded to therapy had a 77% chance of sperm retrieval compared to 55% of men who did not respond to medical therapy (Ramasamy et al., 2009). Y chromosome microdeletions may also affect outcomes of sperm extraction. Men with complete deletions of the AZFa or AZFb regions typically have no chance of sperm retrieval during surgery and it is not recommended to perform micro-TESE procedures (Schlegel, 2009). However, men with AZFc region deletions alone may have a 67% chance of sperm retrieval after micro-TESE (Dabaja and Schlegel, 2013). Other factors that influence outcomes include history of chemotherapy, and cryptorchidism. Patients undergoing chemotherapy are counseled on sperm banking before chemotherapy. In men with cryptorchidism, sperm retrieval is successful if orchiopexy was performed an average of 10 years earlier when compared to men with failed retrieval (Raman and Schlegel, 2003).

Sperm obtained from micro-TESE must be used in intracytoplasmic injection (ICSI)/in vitro fertilization. This is because testicular sperm has not matured and cannot maneuver to the egg as in typical reproduction. The testicular sperm once extracted may be used fresh or frozen. Some embryology labs express concern over cryopreservation of testis sperm due to concern for increased in vitro fertilization failure rates. The freeze-thaw process may result in rupture of the acrosomal and plasma membrane of the sperm, as well as free radical injury that may result in DNA damage (Agca and Critser, 2002). However, the advantages which include the use of sperm obtained in multiple cycles of in vitro fertilization, and allowing the couple the option of waiting for ovarian stimulation and oocyte retrieval while sperm retrieval is undertaken (Fukunaga et al., 2001). Interestingly, recent analysis found no difference in pregnancy rates with fresh surgically retrieved sperm and cryopreserved surgically retrieved sperm. There was also no difference in fertilization rates in these different situations (Ohlander et al., 2014).

Conclusion

Advancement in in vitro fertilization through intracytoplasmic injection (ICSI) has led to continued desire to increase knowledge and improve surgical techniques for sperm retrieval in infertile men. These advances have significantly improved the quality of life of these patients. As not all sperm retrieval techniques are beneficial for certain causes of infertility, it is imperative to be adept in the various techniques and what patient the technique benefits. The primary etiology of the infertility, type of procedure performed and

the ability to adequately retrieve sperm from seminiferous tubules all contribute to the success rate of retrieval. Microsurgical testicular sperm extraction has been proven to be superior when compared to conventional testis sperm extraction technique especially in men with spermatogenic dysfunction.

Glossary

Anejaculation The inability of a male to ejaculate.

Cryopreservation The process by which biological tissues are preserved by cooling to very low temperatures.

Electroejaculation A procedure to obtain semen from male mammals or humans involving placement of an electric probe in the rectum and delivering a voltage to initiate an ejaculation.

Obstructive azoospermia A physical obstruction of the male genital tract that prevents sperm from reaching the ejaculate.

Penile vibratory therapy A procedure to obtain semen from male mammals or humans involving placement of a mechanical vibrating device at the base of the glans penis to initiate an ejaculation with an intact ejaculatory reflex.

Spermatogenesis The process involving development of spermatozoa from spermatogonial stem cells through mitosis and meiosis.

Patient Population and Indications

Sperm can be obtained from men with an obstructive etiology of male infertility with various sperm retrieval techniques when surgical reconstruction is not an option. Obstructive azoospermia is defined as a failure of the sperm to reach the ejaculate due to obstruction in the ductal system. These men typically have normal spermatogenesis—the abnormality is blockage to transport. Vasectomy is the most common etiology of obstructive azoospermia and most of these men are candidates for vasectomy reversal to reconstitute continuity from the testis to the ejaculate. However, there are other causes of obstructive azoospermia that are not amenable to surgical reconstruction. The etiology of obstruction in these men can be congenital or acquired. Such patients are those with congenital bilateral absence of the vas deferens, bilateral partial aplasia of the vas deferens, failed surgical reconstruction, or those with vasal or epididymal obstruction (typically iatrogenic due to vasectomy) that cannot be reconstructed surgically. Additionally, men with anejaculation due to neurologic or psychogenic disorders may be offered these techniques if normal ejaculation is not restored after other treatment modalities have been tried or if the patient prefers. The sperm retrieval techniques discussed in this article enable these men to conceive with in vitro fertilization, a type of assisted reproductive technique. Epididymal sperm are more motile than testicular sperm which confers a theoretical advantage to the techniques discussed in this article as compared to methods to obtain sperm from the testis although fertilization rates using a type of in vitro fertilization called intracytoplasmic sperm injection (ICSI) do not appear to be better using epididymal rather than testicular sperm.

Microsurgical Epididymal Sperm Aspiration

Microsurgical epididymal sperm aspiration (MESA) is a traditional microsurgical approach for obtaining sperm in patients with obstructive azoospermia. Microsurgical skill set and general anesthesia are required. As a result, the overall cost of MESA is higher than percutaneous epididymal sperm aspiration (PESA). A small incision is made in the upper scrotum and the epididymis is identified and examined under the operating room microscope. A dilated epididymal tubule is identified and incised with a micro-knife. The emanating fluid is examined under a microscope. If no sperm are found, the site is closed with microsuture and another site more proximal (closer to the testicle) is found. When motile sperm are found, a micropipette is placed next to the tubule and sperm are drawn in to the pipette which has been preloaded with sperm cryopreservation media. Gentle massage of the testicle and epididymis can be applied to increase yield. Several micropipettes are typically used. Pregnancy rates approach 60% when ICSI is used. Sperm can be used fresh or cryopreserved for future cycles. This technique involves an incision in the skin; therefore, there is a small risk of wound infection and hematoma.

Percutaneous Epididymal Sperm Aspiration

PESA is a procedure that can be performed under local anesthesia without a microsurgical skill set. The procedure involves placing a butterfly needle in to the head of the epididymis after administration of local anesthetic. Negative pressure is applied until a milky white fluid is visualized. The tubing is then clamped and the system is flushed with sperm media in to a collection tube. The procedure can be repeated until sufficient yield is obtained. The percutaneous approach obviates the need to perform a skin incision therefore avoiding the associated morbidity such as infection and pain; however, a small risk of hematoma is still present.

Percutaneous puncture can cause epididymal obstruction due to scarring which may preclude future reconstruction if this is pursued. PESA sperm yield is lower than MESA although usually sperm numbers are adequate for ICSI.

Vasal Aspiration

Vasal aspiration can be performed using percutaneous or open technique. Percutaneous vasal aspiration is performed with local anesthetic. The vas deferens is held between the surgeon's thumb and forefinger in the scrotum. A 21-gauge sharp needle is used to pierce the vas deferens. A 23-gauge blunt needle is then passed through the sharp needle, aiming toward the epididymis. The blunt needle has both a side hole and an end hole. It is connected to a syringe with sperm preservation fluid which is injected gently in to the vas deferens followed by gentle suction. This fluid is then used for sperm cryopreservation or immediate assisted reproductive techniques.

Open vasal aspiration requires a small incision over the spermatic cord in the superior scrotum. The vas deferens is exposed and isolated. The vas deferens is then partially transected with a fine blade. A microaspiration catheter is inserted in the testicular end of the vas deferens. Sperm preservation media is injected gently and aspirated. If sufficient fluid does not return, epididymal massage can be performed. The vas deferens is then closed with microsuture—this can be done with the microscope or loupe magnification depending on surgeon experience. Vasal aspiration may create an obstruction from the procedure itself which would preclude future surgical reconstruction if the patient is considering this option in the future.

Summary

Men with obstructive azoospermia or anejaculation are candidates for several sperm retrieval techniques including PESA, MESA, and vasal aspiration. Each technique has specific risks and benefits, and success rates vary among them.

Introduction: What Is Penile Vibratory Stimulation (PVS) and What Are Its Uses?

PVS, for the purposes of this chapter, is the application of a vibrator(s) to the penis in order to elicit a reflex ejaculation in men who are anejaculatory. Its main application is in the field of fertility management in men who have suffered a spinal cord injury (SCI) or suffer from a congenital disease or a disease or process in the spinal cord which results in neurogenic anejaculation.

History

The history of the use of PVS might be described by answering the question: "What good is sperm retrieval if we don't know what to do with the sperm after we get it?" The history of the use of sperm retrieval techniques in men with SCI-related ejaculatory dysfunction is interwoven with the use of artificial insemination, primarily intravaginal insemination, in veterinary/animal husbandry practice; the development of current assisted reproductive technologies (ARTs); the current age of information and communication; and the emergence of an informed SCI population. John Hunter is credited with the first artificial insemination in humans in the late 1700s. It was, in fact, an intravaginal insemination of sperm in a couple where the husband had hypospadias (Gutmacher, 1943). However, artificial insemination of this type plays a greater role in animal husbandry and the conservation of endangered species than in the management of couples who have difficulties in conceiving. (An exception exists in human infertility practice, where intravaginal insemination using ejaculates obtained using PVS in men with SCI is used successfully by many practitioners.)

In more current times, 1978 is considered a pivotal year. The world was told by Steptoe and Edwards of the first human live birth after IVF. Prior to this time, there were many descriptions of intravaginal artificial insemination and at least one report of intra-uterine insemination (IUI). In this 1941 report, 6 of 148 women became pregnant via IUI. Publications in the 1940s and 1950s described improvements in sperm preparation for insemination and sperm freezing. This led to the notion that infertile men could become biologic fathers. The later success of IVF in the 1980s spurred renewed interest in the use of IUI as well, based in part on what was learned in the earlier studies of sperm preparation (Gutmacher, 1943; Ombelet and Van Robays, 2015).

In 1981, Brindley described his experience with penile vibratory stimulation (PVS) and electroejaculation (EEJ) in men with spinal cord injuries (Brindley, 1981a,b). Although he was not the first, he was considered a champion of sperm retrieval in men with SCI. In 1987, a review coauthored by Stephen Seager, DVM, reviewed five previous reports of the use of electroejaculation. Seager described his own results in spinal cord injured patients (Halstead et al., 1987). Dr. Seager also developed a much needed tool: a reliable, safe, and eventually FDA-approved device for performing EEJ in humans. He had a significant prior experience in the use of EEJ in animals. The reliability and reproducibility of the EEJ device, allowed for the first time, collection of semen for the accumulation of data to study the condition of infertility in men with SCI.

Prior to the 1990s, the use of vibratory stimulation to the penis had been described, but had been used only sporadically by researchers and clinicians to obtain an ejaculate. In 1994, Sonksen showed that there was an optimal vibrator head frequency and amplitude in the application of PVS, which resulted in improved sperm quality versus non-optimized vibrators (Sonksen et al., 1994). These findings led to the development of the Ferticare device, which was specifically engineered to induce ejaculation in men with neurogenic anejaculation. In patients who were responsive to PVS, this method proved to be easier, quicker, and produced a higher quality ejaculate than EEJ (Sonksen et al., 1994).

More recent developments have further enhanced treatment of infertility in men with SCI. By the late 1980s, the internet was considered mainstream at most universities in the US, and mainstream in most US households by the late 1990s. The flow of information about any subject became as easy as entering queries into ever-improving applications and search engines. Second, the Americans with Disabilities Act, ADA, was signed into law in 1990, and persons with SCI began to seek the care they were entitled to. More recently, another FDA-approved device, the ViberecX3 (Reflexonic, Frederick, MD, USA), has been introduced for use in sperm retrieval in men with SCI. The ViberecX3 uses two vibrating pads (Fig. 1).

Why PVS?

There are two well-established and well-studied methods for sperm retrieval in men who have neurogenic anejaculation, EEJ and PVS. EEJ is successful in producing an ejaculate in over 95% of the spinal cord injured population. In common usage however, it is reserved for those persons who do not respond to PVS. EEJ is discussed in detail in another chapter. Compared to EEJ, PVS is easier to use, can produce an ejaculate in the majority of men with SCI lesions at T10 or above, and produces antegrade ejaculates with a higher percentage of motile sperm. In carefully selected and trained couples, it can be performed at home for use in intravaginal insemination (Ibrahim et al., 2016b).

Fig. 1 Optimized vibrators for PVS: left: Ferticare; right: Vibrect X-3.

SCI: The Neurogenic Anejaculation Paradigm

SCI is the paradigm for illustrating the neural pathways necessary for normal ejaculation and the sequelae of neurogenic dysfunction in those areas. Normal ejaculation depends on intact neural pathways for the coordinated components of ejaculation, emission, and expulsion. Emission for the most part relies on sympathetic nervous output, T10–L2. Expulsion for the most part relies on parasympathetic output, S2–S4. The dorsal nerve of the penis, a branch of the pudendal nerve, S2–S4, is a necessary component providing somatic sensory input into the ejaculatory reflex arc. Motor branches of the pudendal nerve to the pelvic floor and external urinary sphincter are involved in the expulsive phase as well. A spinal generator of ejaculation located approximately at L3 orchestrates the somatic, sympathetic, and parasympathetic innervated anatomical structures participating in ejaculation. When the spinal cord is intact, supra-spinal input, both facilitative and inhibitory, moderate this complex reflex activity (Fode et al., 2015).

Some things become apparent in looking at this scenario. Persons with spinal cord injuries rostral to T10 should have their entire reflex components intact and respond to an adequate penile vibratory stimulus. These persons are the ideal candidates for PVS. Persons with injuries to the cord below T10 should be poor or no responders to an adequate stimulus. Persons with injuries to the lower sacral segments, or to the pudendal nerve may not respond to any stimulus if their lesion precludes transmission of the stimulus into the spinal cord.

The stimulus produced via sexual activity, usually is not enough on its own to initiate a reflex ejaculation in the SCI patient; hence only about 10% of men with injuries at or rostral T10 report the ability to ejaculate by masturbation or sexual intercourse. The stimulus produced by an optimized vibrator, however, will induce a reflex ejaculation in up to 85% of such patients, and 15%–17% of men whose injury is below T10 (Brackett et al., 2010). The intensity of stimulus necessary to induce ejaculation in men with SCI is considered painful to most neurologically intact men.

A Word of Caution

The overwhelming majority of patients who will respond to PVS will do so within the first 12 months post injury, however, some will not respond for up to 18 months post-injury. In practice, we do not delay attempting a trial of PVS if the patient so desires early after injury, but he is counseled that if there is no response, we will make another attempt in 3–6 months.

The Procedure

Prior to the actual performance of the PVS procedure, patient should have a history and physical exam. The presence or absence of a bulbocavernosus reflex and hip flexor reflex should be determined (see the section on results), the patient should be pre-treated for autonomic dysreflexia (see below), and the bladder prepared for sperm retrieval if needed as described below. The patient should be advised that certain somatic responses are often seen as the PVS stimulation progresses. These usually occur below the level of injury and may include sweating, flushing, other symptoms of autonomic dysreflexia, and greatly increased levels of spasticity. If the intercostal muscles are involved, the patient may experience a feeling of tightness in the chest or a feeling of difficulty breathing. There may be strong abdominal contractions which sometimes will become rhythmic just before ejaculation. An erection may occur immediately prior to ejaculation but is not necessary for ejaculation to occur. After the procedure is over, the patient may complain of a decrease in both muscle tone and spasticity, which occasionally may be disturbing to them. This period of flaccidity may last from minutes to hours and its occurrence is not predictable. For such patients, it may be advisable for someone to accompany the patient and drive him home. Alternatively, the patient should be prepared to wait until his normal muscle tone reappears.

Autonomic Dysreflexia

Autonomic dysreflexia (AD) is a condition wherein the thoracolumbar sympathetic nervous system reacts to a stimulus in an unmitigated and unregulated manner. This may result in symptoms ranging from mild discomfort to extremely severe and occasionally damaging hypertensive crises. This situation occurs in persons with spinal cord injuries at or above the level of T6, interrupting the supraspinal input which normally moderates this reflex response. The stimulus may be as simple as a full bladder, or may be triggered by external stimuli such as application of an intense vibrator to the penis as in PVS. It has been our practice to pre-medicate all patients, whose level of injury is T6 or higher, with the administration of nifedipine prior to starting the procedure. Other methods of management such as the use of nitro paste or Prazosin have been employed successfully.

Some patients may experience uncomfortable symptoms at what would otherwise be considered modest increases in blood pressure, whereas other patients may have startlingly high elevations in blood pressure with no symptoms. Patients' self-reporting of having experienced autonomic dysreflexia may often be inaccurate. For these reasons we have observed a few simple rules during the conduct of a PVS trial. First, all patients are monitored continuously with pulse and blood pressure readings taken each minute after the trial has started. Second, the trial will be discontinued if the patient experiences any uncomfortable symptoms, regardless of the blood pressure reading, and will be discontinued if the blood pressure reaches a preset limit, regardless of the symptoms. Finally, all patients that have a spinal cord lesion at T6 or rostral will be pretreated with nifedipine (20 mg initially). A wider ranging discussion of autonomic dysreflexia can be found in an excellent article by [Krassioukov et al. \(2009\)](#).

Bladder Preparation

Although the majority of PVS procedures will result in little or no retrograde component, if an ejaculate is obtained that is considered poor or inadequate for its intended purpose, the practitioner may wish to determine if any additional sperm can be retrieved from the bladder. If the practitioner knows that this may be the only visit he will have with the patient and the intended use for this visit's ejaculate will be for the purpose of an ART procedure, it is advisable then to prepare the bladder and obtain a post ejaculatory sample for inspection.

Details of the PVS Procedure

Generally two medical personnel will be needed to perform a PVS procedure. One person will steady the penis and apply the vibrator while a second person holds the sterile specimen cup close to the urethral meatus to collect the ejaculate. The collector usually is positioned on the opposite side of the person who applies the vibrator. Blood pressure should be monitored each minute of the procedure. This is best accomplished with a device that allows automatic recordings at time intervals that can be set by the operator. We set the alarms at systolic BP of 140 mmHg and diastolic of 100 mmHg. The meatus and glans should be cleaned with soap and water or an alcohol swab that allows it to dry in order to minimize the chance of contaminating the specimen and injuring the sperm.

Prior to the procedure, the patient is usually transferred to an exam table. Almost any position on the table is acceptable as long as the operators have comfortable access to the genitalia. (In some patients, it may be possible for the PVS procedure to be performed with the patient seated or reclined in his wheelchair, although this is a bit more cumbersome.) The vibrator is applied to the glans in an area that allows the collector access to the meatus. Some patients may experience stronger sensations in a particular area of the glans. In general, however, we have not noticed any difference in response if the vibrator is placed on the dorsum of the glans (the most convenient place for collection), versus the frenulum (more problematic when collection is involved) ([Fig. 2](#)).

Fig. 2 PVS performed with one vibrator.

The vibrator is applied for 2–3 min then stopped and the skin of the glans inspected for any early signs of damage or abrasion. Caution should be exercised in the amount of pressure used when applying the vibrator to the penis in men who have an underlying penile prosthesis. Additionally, in men who wear external urinary collection devices one should be aware the skin of the glans may be chronically inflamed to some degree and thus more sensitive to the abrasive effects of the vibrator. If necessary, the procedure can continue for up to 10–12 min so long as there is no damage to the skin of the glans. In practice, the majority of the men will ejaculate in less than 2 min.

Results and Clinical Applications

With the exception of select couples who may be able to learn and use intravaginal insemination at home, most couples require some form of assisted reproductive technique, such as intrauterine insemination or in-vitro insemination, to achieve pregnancy. In these cases, all other things being equal, the choice of technique is usually driven by the total number of motile sperm available in the ejaculate. Sperm concentration and sperm motility is typically higher in antegrade ejaculates produced by PVS compared to EEJ (Table 1).

Wherever possible, antegrade versus retrograde ejaculates are preferred for use in the ART. Experience with a large number of men with SCI has allowed us to develop an algorithm (Fig. 3) for semen retrieval in these men with an emphasis on identifying as many men as possible who could be candidates for PVS (Brackett et al., 2010).

Some men may not ejaculate on their first trial with an optimized vibrator, that is a single Ferticare. The reader's attention is directed to the portion of the algorithm contained within the black rectangular outline. This section of the algorithm deals with the most critical information, that is, how to identify the men who fail to ejaculate with their first trial of PVS that might benefit from a second trial of PVS with the use of two vibrators. The algorithm is based on the presence or absence of the bulbocavernosus reflex (BCR), the hip flexor reflex (HR), level of injury (LOI), and the presence of certain somatic responses seen during the first trial (Bird et al., 2001).

The Critical Information in More Detail

The first level of determination: Level of injury (LOI)

Cervical: If the patient's LOI is at a cervical segment, the presence or absence of the BCR or HR is no more predictive of a response than the LOI itself.

T1–T6: If the patient's LOI is between T1 and T6, the presence of at least one reflex is favorable. The absence of both reflexes is predictive of no response to PVS.

T7–T12: If the patient's LOI is between T7 and T12, those with no BCR are poor candidates and should go to EEJ.

The next level of determination: Somatic responses

While many somatic responses are commonly seen in men undergoing PVS, the following are seen more often in men who respond to PVS versus non-responders: piloerection; withdrawal responses; new or increased extremity spasms; thigh abduction. When the LOI and somatic response criteria are used to identify men who may be responders to PVS, more than 20% of men who initially fail a trial with one Ferticare vibrator will be found to respond to either a second trial of one vibrator or a trial using the application of two vibrators simultaneously (Fig. 4).

If one is assiduous in making all the efforts in identifying all candidates for PVS, the success rate of ejaculation using PVS is 86% if the LOI is T10 or higher, and 15% if the LOI is T11 or lower (Brackett et al., 2010).

Sperm Quality

In any given trial of PVS in which an antegrade ejaculate is obtained, no sperm will be seen approximately 10% of the time; 5 million or less total motile sperm (TMS) will be seen approximately 25% of the time; greater than 20 million will be seen approximately 45% of the time and 5–20 million TMS will be seen approximately 20% of the time (Kafetsoulis et al., 2006). The relevance of the numbers of motile sperm seen in an ejaculate is that, in general, most practitioners will be comfortable attempting IUI with

Table 1 Comparison by method of antegrade semen quality in men with SCI

	Control (non-SCI)	Semen quality in antegrade ejaculates		
		Masturbation (SCI)	PVS (SCI)	EEJ (SCI)
No. of subjects	61	43	243	158
Mean volume $\pm$ SEM (cc)	3.0 $\pm$ 0.2	2.2 $\pm$ 0.2	1.9 $\pm$ 0.1	1.2 $\pm$ 0.1
Mean count/cm ³ $\times 10^6 \pm$ SEM	82.0 $\pm$ 5.4	83.3 $\pm$ 0.3	77.4 $\pm$ 5.0	49.9 $\pm$ 5.2
Mean % motility $\pm$ SEM	58.0 $\pm$ 1.5	36.9 $\pm$ 3.3	25.9 $\pm$ 1.2	15.0 $\pm$ 1.2

ALGORITHM FOR SPERM RETRIEVAL IN MEN WITH SPINAL CORD INJURY

Fig. 3 Algorithm for sperm retrieval: Attention is paid to the information within the outlined box.

Fig. 4 PVS performed with two vibrators.

the number of motile sperm inseminated starting at 5 million; lower numbers of motile sperm being used for IVF/ICSI. For most of the couples who have intravaginal insemination recommended, 15–20 million motile sperm will be a starting point.

Pregnancy Rates

Pregnancy rates following assisted reproduction procedures using ejaculated sperm from men with SCI are similar to those seen in non-injured men with male factor infertility. For IUI, one study by our group found per cycle fecundity rate of 7.9%, similar to the rates published for non-injured men with male factor infertility. Likewise, another study compared IVF/ICSI fertility rates per couple in men with SCI to those with non-injured male partners and found them essentially the same, 58.1% versus 57.9%. While there are no strict guidelines relating to the procedure, published studies of at home intra-vaginal insemination in couples with a male partner with SCI report pregnancy rates of 25%–70% (Ibrahim et al., 2016a; Kathiresan et al., 2011a,b).

Sperm Retrieval From the Bladder

Nancy L Brackett, Emad Ibrahim, and Charles M Lynne, University of Miami Miller School of Medicine, Miami, FL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

In normal ejaculation, sperm exit the urethral meatus during orgasm (antegrade ejaculation), and very few, if any sperm enter the urinary bladder (retrograde ejaculation). Certain medical conditions, however, lead to retrograde ejaculation, and this condition may interfere with the man's ability to initiate a pregnancy by sexual intercourse. If pregnancy is a goal, it may be necessary to retrieve sperm from the bladder for use in assisted conception procedures. This article will describe methods of retrieving sperm from the urinary bladder.

Retrograde Ejaculation

Normal ejaculation is mediated by a combination of peripheral, cerebral, and spinal sensory and motor neuron pathways. Sympathetic nerves arising from the T10–L2 spinal level mediate contraction of the emission phase of ejaculation in which the prostate and seminal vesicles deposit seminal fluid into the posterior urethra, with simultaneous closure of the bladder neck to prevent retrograde flow of semen (Thomas, 1983). Somatic nerves arising from the S2–S4 spinal level mediate the expulsion phase of ejaculation in which pulsatile contraction of the bulbocavernosus and pelvic floor muscles, together with relaxation of the external urinary sphincter to promote antegrade seminal emission (Thomas, 1983). During the expulsive phase of ejaculation, the internal urethral sphincter (the bladder neck) closes to prevent semen from entering the bladder. If the bladder neck fails to close adequately, semen can reflux into the bladder. This condition is known as retrograde ejaculation.

A man with the condition of retrograde ejaculation may have low-volume or no antegrade ejaculate. Consequently, little or no sperm may be available for conception by sexual intercourse. Medical conditions that can contribute to retrograde ejaculation include:

- Surgery, such as bladder neck surgery, retroperitoneal lymph node dissection or prostate surgery.
- Side effect of certain medications used to treat high blood pressure, prostate enlargement, or depression.
- Nerve damage caused by a medical condition, such as diabetes, multiple sclerosis, Parkinson's disease, or spinal cord injury.

Initial Diagnosis

Typically, an initial diagnosis of retrograde ejaculation is made. This diagnosis is followed by decisions regarding if, when, and how to treat the retrograde ejaculation. The initial diagnosis of retrograde ejaculation includes a postejaculatory urinalysis (PEU). The PEU is performed by asking the patient to masturbate until he feels sexual climax. Any antegrade ejaculate (even a small volume) that accompanies the climax should be collected in a specimen cup. The specimen cup should be nontoxic to sperm. The patient is instructed to then urinate into one or more additional specimen cups. Prior to performing masturbation for the PEU procedure, it is helpful for the patient to urinate without completely emptying. This step will help reduce the volume of postejaculatory urine that must be processed for sperm isolation.

The most accurate PEU results are usually obtained when masturbation and urine collection is performed in the clinic. The patient performs these activities privately in a designated semen collection room, or other appropriately-outfitted procedure room. The clinic setting allows personnel the most rapid access to the patient's urine specimen for processing and analysis. If it is not possible for the patient to perform masturbation and urine collection in the clinic, then the patient may perform these activities at home and bring the specimen cups to the clinic for analysis. Specimen collection times should be noted, because prolonged exposure of sperm to urine can be detrimental to sperm quality. For the initial diagnosis of retrograde ejaculation however, the quality of sperm may be less critical than simply noting the quantity of sperm in the urine. Future collections of sperm from the bladder can be optimized for assisted conception procedures.

Analyzing Sperm Collected From the Bladder

If the patient has properly collected his specimen for PEU, there will be one or more specimen cups of the patient's urine voided after he achieved orgasm. In addition, if the patient produced an antegrade ejaculate upon climax, there will be a specimen cup containing his antegrade semen specimen. The antegrade semen specimen should be analyzed according to the laboratory's routine protocol for semen analysis. The retrograde ejaculate should be analyzed by first measuring the total volume of urine voided. Depending on this total volume, all of the urine, or a portion of the urine, should be centrifuged and the pellet examined for sperm. Calculations are then made (see below) to determine the total sperm count in the retrograde ejaculate. The reason total sperm count

is calculated, rather than sperm concentration (sperm count/cm³ semen), is that the volume of semen released into the bladder is unknown during retrograde ejaculation. Therefore, in terms of sperm count, only the total number of sperm obtained from the bladder can be determined.

Calculating Total Sperm Count From the Bladder

To calculate the total number of sperm obtained from the bladder, the pellet of centrifuged urine is examined. The sperm count/cm³ of urine pellet is determined. This value is then multiplied by the volume of the pellet. This value is then multiplied by the portion of total voided urine it represents.

For example:

If the total volume of voided urine = 100 cm³.

If the volume of urine centrifuged = 20 cm³.

If the volume of the urine pellet = 0.4 cm³.

If the sperm count/cm³ urine pellet = 8 million sperm.

The calculation is: 8 million sperm × 0.4 cm³ pellet = 3.2 million sperm in 20 cm³ of urine = 16 million total sperm in 100 cm³ of urine (i.e., total sperm count in the retrograde ejaculate).

Treating Retrograde Ejaculation

After a diagnosis of retrograde ejaculation has been made, the physician will consult with the patient about the patient's goals. If pregnancy by sexual intercourse is a goal, then a concomitant goal will be to improve the volume of antegrade ejaculate produced by the patient. Medical therapies are typically recommended for this purpose. For example, oral sympathomimetics have been successful in restoring antegrade ejaculation in 50%–100% of cases, and these agents are often considered first-line therapy for the treatment of retrograde ejaculation ([Mehta and Sigman, 2015](#)).

Preparing the Bladder for Retrograde Ejaculation

When retrograde ejaculation is not responsive to medical therapy, and the patient wishes to achieve pregnancy, urinary sperm retrieval is the most commonly described technique to obtain sperm for use in assisted conception procedures. When a procedure is planned in which sperm retrieved from the bladder will be used to attempt pregnancy, then it is important to maximize the quality of sperm that is retrieved from the bladder. The urine in the bladder can be detrimental to the quality of sperm that comes into contact with it during retrograde ejaculation ([Voge et al., 2016](#)). Specifically, the acidic pH of urine, among other variables, can be detrimental to sperm motility ([Makler et al., 1981](#)). Consequently, alkalization of the bladder is often attempted prior to procedures in which sperm retrieval from the bladder are planned. Systemic approaches to alkalization include oral administration of agents such as acetazolamide, baking soda, and potassium citrate ([Mehta and Sigman, 2015](#)). Additionally, in patients who can tolerate urinary catheterization, placement of sperm-washing medium may be instilled into the empty bladder before ejaculation. This step should be performed immediately (within 10 min) prior to the ejaculation procedure.

Ejaculation Procedure

To maximize the number of sperm available for assisted conception, the man should abstain from ejaculation for 2–5 days prior to the ejaculation intended for assisted conception. If the man is aspermic, he should be specifically instructed to abstain from bringing himself to orgasm for 2–5 days prior to the ejaculation intended for assisted conception. This interval of abstinence has been shown to optimize sperm counts between ejaculations ([World Health Organization, 2010](#)). Immediately (within 5 min) prior to performing masturbation to produce the retrograde ejaculate, the patient should be instructed to urinate into the toilet until his bladder is nearly empty. Next, in a private collection room, the patient should masturbate until he feels sexual climax. If any antegrade ejaculate is produced, he should collect it in a specimen cup that is nontoxic to sperm. Next, the patient should urinate into an additional specimen cup. If that cup becomes full, he should urinate into a second cup, etc. Rarely are more than two cups needed if the patient has urinated prior to masturbation.

Isolating the Sperm From the Urine Specimen

When sperm from a retrograde ejaculate are intended for use in an assisted conception procedure, it is best for the patient to perform masturbation in the clinic versus at home. By doing so, the postejaculatory urine can be processed as rapidly as possible to isolate the sperm from urine, and thereby reduce the exposure time and detrimental effect of urine on sperm. Prior to processing the urine, the total volume of urine voided into the specimen cups should be measured. Next, the total volume of urine should be centrifuged for the purpose of obtaining all of the available sperm from the bladder for use in the assisted conception procedure. A brief and gentle centrifugation, such as 300 × g for 5 min, is typically sufficient to isolate the sperm into a pellet. The total sperm count can be

calculated as described above. In addition, sperm motility should be determined according to the laboratory's protocol for assessing sperm motility. Ultimately, the total motile sperm count can be calculated ($\text{total sperm count} \times [\% \text{ of motile sperm}/100]$). The total motile sperm count is often used for deciding which assisted conception procedure will be used to achieve pregnancy. Options may include intrauterine insemination (or possibly even intravaginal insemination), in addition to in vitro fertilization, with or without intracytoplasmic sperm injection. Further processing of the retrograde semen specimen may be necessary, depending on the laboratory's protocols. For example, a swim up procedure or gradient processing may be used to further isolate the most motile sperm for use in assisted conception.

Pregnancy Rates

No studies have compared the effectiveness of various regimens of alkalization on sperm motility or on pregnancy outcomes. Pregnancy rates with the use of sperm retrieved from the bladder have been reported. For example, pregnancy rates with intrauterine insemination vary from 20% to 50% (Mehta and Sigman, 2015). In vitro fertilization and intracytoplasmic sperm injection are options for couples that fail repeated cycles of intrauterine insemination, and for couples where a concomitant female factor may also be present. There is a need for better-quality prospective studies specifically designed to compare treatment options for aspermia. In cases where sperm are retrieved from postejaculate urine, there is an additional need for studies comparing reproductive outcomes following intrauterine insemination versus in vitro fertilization with or without intracytoplasmic sperm injection.

Surgical Options

A review by Mehta and Sigman notes that surgical options for the treatment of retrograde ejaculation are limited to reconstruction of the bladder neck and have been described by only two small series. Although both series noted highly successful outcomes, surgical treatment is largely historical and should be reserved as the last course of therapy for patients with retrograde ejaculation and must be weighed against urinary sperm retrieval and assisted reproductive technologies (Mehta and Sigman, 2015).

Men With Spinal Cord Injury

Men with spinal cord injury represent a unique group of patients with retrograde ejaculation. Their neurological damage results in an inability to ejaculate by sexual intercourse or masturbation in 90% of patients (Brackett et al., 2010). Consequently, those who wish to become biological fathers must have their sperm retrieved by medical procedures. Semen collection by medically assisted ejaculation should be attempted first, prior to sperm retrieved by surgery from reproductive tissues. Higher numbers of motile sperm can usually be obtained from the ejaculate versus from reproductive tissues such as the testis or epididymis. When higher numbers of motile sperm are available, then more options for assisted conception are possible.

For example, 5 million or more motile sperm can be obtained from most assisted ejaculation procedures of men with spinal cord injury (Brackett et al., 2010). This number of motile sperm is sufficient for most practitioners to consider intrauterine insemination, or possibly even intravaginal insemination. In contrast, when <5 million motile sperm are available (the number usually obtained with surgical sperm retrieval) the couple usually must undergo in vitro fertilization with intracytoplasmic sperm injection to achieve pregnancy. The procedure of in vitro fertilization (with or without intracytoplasmic sperm injection) is more costly than the procedures of intravaginal insemination or intrauterine insemination, that is, \$10,000–\$15,000 per attempt of in vitro fertilization versus \$0–\$1500 per attempt of intravaginal insemination or intrauterine insemination. In addition, the procedure of in vitro fertilization can add risk to the female partner relative to intravaginal insemination or intrauterine insemination (Winston and Hardy, 2002). For these reasons, it is recommended that the ejaculate (antegrade and/or retrograde) be examined before performing surgical sperm retrieval in patients with spinal cord injury.

Assisted Ejaculation in Men With Spinal Cord Injury

To obtain the ejaculate from an anejaculatory man with spinal cord injury, the methods of penile vibratory stimulation or electroejaculation are often used (Ibrahim et al., 2016a). These procedures are described in detail in other articles, and will be only briefly summarized here. The method of penile vibratory stimulation should be attempted prior to the method of electroejaculation because, relative to electroejaculation, penile vibratory stimulation is less invasive, is preferred more by patients, and results in a higher number of motile sperm in the antegrade ejaculate (Ibrahim et al., 2016b).

Penile vibratory stimulation is performed by applying, to the glans penis, a vibrating device which delivers mechanical stimulation to induce ejaculation. The device should be optimized to deliver an amplitude of 2.5 mm. This amplitude results in a higher response rate than lower amplitudes (Sonksen et al., 1994; Brackett et al., 2010). If the patient fails to respond to the application of one device, then two devices may be applied. In the two-device method, the penis is sandwiched between one device placed on the dorsum of the glans penis and one device placed on the frenulum of the glans penis. This "sandwich" method can salvage failures to one device (Brackett et al., 2007).

Patients who fail to respond to the application of one or two vibrators should be referred for the alternative assisted ejaculation procedure of electroejaculation. The method of electroejaculation is performed by inserting a probe into the patient's rectum. Current is delivered through electrodes positioned on the probe. Increasing amounts of current result in ejaculation. Detailed information about the application of penile vibratory stimulation and electroejaculation are provided in other articles.

Retrograde Ejaculation in Men With Spinal Cord Injury

The methods of penile vibratory stimulation or electroejaculation can result in retrograde ejaculation in men with spinal cord injury. Retrograde ejaculation is more likely to occur with electroejaculation than with penile vibratory stimulation (Brackett et al., 1997). Consequently, in electroejaculation procedures performed to obtain sperm for diagnosis or assisted conception, it is recommended that the bladder be prepared to optimize sperm quality obtained from the bladder. Preparation of the bladder may be similarly performed prior to penile vibratory stimulation procedures, however, retrograde ejaculation may not occur in many cases of penile vibratory stimulation. The practitioner's judgment is the best guide for deciding on preparation of the bladder prior to penile vibratory stimulation. In our work with 3540 penile vibratory stimulation procedures in 671 men with spinal cord injury, we have found that presence or absence of retrograde ejaculation is a consistent finding, trial to trial, within each patient. Therefore, if retrograde ejaculation is present in the first two trials of penile vibratory stimulation in a particular patient, we will prepare the bladder on future trials of penile vibratory stimulation in that patient. In contrast, if retrograde ejaculation is absent in the first two trials of penile vibratory stimulation in a particular patient, we will usually not prepare the bladder on future attempts of penile vibratory stimulation in that patient.

Preparing the Bladder for Retrograde Ejaculation in Men With Spinal Cord Injury

Most men with spinal cord injury are unable to void spontaneously. Therefore, urinary catheterization is necessary to drain the patient's bladder to prepare it for retrograde ejaculation. Urinary catheterization can be performed by the patient or by medical personnel assisting with the ejaculation procedure. Sterile technique should be used for urinary catheterization. A nonspermicidal lubricant should be used. After the urine has been drained, the catheter should be left in place, and 25–50 cm³ of sperm washing medium instilled through the catheter into the bladder. The catheter is then withdrawn from the bladder. The bladder should be prepared immediately (not more than 10 min) before the ejaculation procedure, to minimize accumulation of urine. Some practitioners may opt to also treat the patient with systemic alkalization. Our experience has shown that systemic alkalization may lead to gastric upset in some men with spinal cord injury, and provide little or no alkalization secondary to the instillation of sperm washing medium into the bladder (unpublished data). Consequently, we do not routinely treat men with spinal cord injury with systemic alkalization.

For patients whose bladders are managed with suprapubic catheters, the following may be done to prepare the bladder for retrograde ejaculation. First, the bladder should be lavaged with aliquots of normal saline until no sediment is seen in the fluid. Lavage should be repeated once or twice with the sperm washing medium. Finally, 25–50 cm³ of sperm washing medium should be left in the bladder. The suprapubic tube is clamped during the ejaculation procedure. A collection cup should be held at the meatus as the suprapubic tube does not preclude antegrade ejaculation.

Collecting the Retrograde Ejaculate in Men With Spinal Cord Injury

After the assisted ejaculation procedure is concluded, the bladder contents should be drained as soon as possible to process the retrograde specimen and isolate the sperm from the urine. Urinary catheterization using sterile technique should be performed to drain the bladder contents, with a nonspermicidal lubricant to help insert the catheter into the urethral meatus. With the catheter left in place, another 25–50 cm³ of sperm washing medium can be used to lavage the bladder to extract any residues of ejaculate that may have fallen to the floor of the bladder and were thus not captured easily during the initial draining. We perform a second lavage if the first lavage contents are cloudy. For our purposes, we label the cup containing the initial bladder drain contents as "R1" (for retrograde fraction 1) and the lavaged fractions as "R2" and "R3." Often, the semen quality of a lavaged fraction (R2 and R3) is better than the initial fraction (R1).

Isolating Sperm From the Bladder Contents in Men With Spinal Cord Injury

After an ejaculation procedure is complete, the urine should be obtained and processed as soon as possible to minimize exposure of sperm to urine. The various fractions collected (R1, R2, R3, etc.) should not be combined before processing because one of the fractions may have superior sperm quality for use in assisted conception, that is, using sperm from the superior fraction may be optimal for the chosen assisted conception procedure (versus using sperm from all of the fractions).

To isolate the sperm from the urine, pipet the urine into centrifuge tubes labeled R1, R2, R3, etc., as appropriate. Centrifuge at 300 × g for 5 min to pellet the sperm. Examine the pellets from R1, R2, R3 separately, and decide which pellets contain the sperm

that will be used in the assisted conception procedure. Depending on the laboratory's protocols, additional processing, such as a swim up procedure or a density gradient procedure, may be necessary to isolate the most motile sperm for use in assisted conception.

Conclusion

Retrograde ejaculation can interfere with a man's ability to achieve pregnancy by sexual intercourse. An initial diagnosis of retrograde ejaculation includes a postejaculatory urinalysis. Once the diagnosis of retrograde ejaculation is made, decisions are discussed with the patient regarding treatments. For patients who wish to attempt pregnancy by sexual intercourse, treatments that attempt to reverse retrograde ejaculation are recommended. When these treatments are not effective, then sperm retrieval from the urinary bladder may be performed to obtain semen for assisted conception. Men with spinal cord injury represent a specialized group of patients with retrograde ejaculation. Most men with spinal cord injury cannot ejaculate by sexual activity or void voluntarily. Semen retrieval procedures may be performed to obtain semen for assisted conception. These procedures may result in retrograde ejaculation. Bladder preparation prior to semen retrieval can optimize the quality of sperm obtained from the bladder. More studies are needed that compare pregnancy outcomes using sperm retrieved from retrograde versus antegrade semen specimens.

Glossary

ART Assisted reproductive technologies.

TESA Testicular sperm aspiration. A method of retrieving sperm using needle aspiration and negative pressure.

TESE Testicular sperm extraction. Sperm retrieval from an open biopsy of testicular tissue.

ICSI Intracytoplasmic sperm injection. Introduction of processed sperm into an egg, enabling fertilization with sperm of unsatisfactory quantity and quality.

Oligospermia Low sperm count. According to the most recent WHO definitions (2010), a sperm concentration of 15 million per milliliter or less in the human ejaculate. Oligospermia is correlated with a lower pregnancy rate.

Introduction

It is widely recognized that cancer survivors are at a significant risk of infertility due to their disease and treatment related toxicities. Chemotherapy and radiotherapy incur deleterious effects on spermatogenesis and may result in temporary or permanent gonadal toxicity. There were an estimated 14.1 million cancer cases around the world in 2012 (of these, 7.4 million cases were in men), and this number is expected to increase to 24 million by 2035. In the US, approximately 9% of cancers in males were diagnosed in patients under the age of 45, and up to 1.1% are under the age of 20 (Siegel et al., 2014). Marked advances in the field of oncology have led to increased survival in young men with cancer. For example, between 2001 and 2012, the five-year survival rate for male cancer patients under the age of 45 in the US was over 75%. Improved survival rates, together with the explosive breakthroughs in the field of assisted reproduction, drove patients and caregivers to extend their focus toward fertility preservation. Since the introduction of sperm cryopreservation in the 1960s and the developments in assisted reproduction in the 1970–1980s, fertility preservation for cancer patients has been practiced sporadically. Increasingly, guidelines of various associations unequivocally called for a discussion of fertility preservation with all cancer patients of reproductive age (and with parents or guardians of children and adolescents) if infertility is a potential risk. The growing interest in this field has culminated in the coining of a new term in 2006: “oncofertility.” This term describes the integration of different specialties into a new subspecialty focused on the reproductive future for cancer survivors. This article will focus on the various aspects of oncofertility in the male cancer patient, its significance, optional treatment modalities, and future perspectives.

The Effects of Cancer and Cancer Therapies on Male Fertility

The Effects of Cancer on Male Fertility

Men with certain types of cancer may be at increased risk of lower semen parameters, and consequently, subfertility (Moss et al., 2016). Testis cancer, lymphoma, and leukemia patients are more likely to present with lower motile sperm counts compared to patients with other types of cancer, and are at higher risk of azoospermia. There are multiple possible causes for poor sperm quality in the oncological patient, including endocrine disturbances (disruption of the hypothalamic-pituitary-gonadal axis, production of hormones by the cancerous tissue), cytotoxic autoimmune response and other systemic effects of cancer, disease related catabolic state or dietary deficiencies, local tumor effects, and inborn impairment in the spermatogonial germ cells (Williams et al., 2009).

Table 1 summarizes the possible negative effect of cancer and its treatments on various physiologic mechanisms related to fertility.

The Effects of Radiation Therapy on Male Fertility

Radiation is employed in the treatment of various types of cancers, such as brain, bladder, rectal, testicular, or hematologic cancers. Spermatogenesis is extremely sensitive to radiation induced damage. Direct radiation to the testis at a dose as low as 0.1 Gray (Gy) may damage spermatogonia and disrupt spermatogenesis (Agarwal et al., 2014). More commonly, damage to the testis occurs through scatter from radiation directed at other structures or whole body radiation, rather than direct radiation to the testis (Meistrich, 2013). Unfortunately, even though protective lead shields are used, some scatter radiation is unavoidable (Moss et al., 2016). Several factors influence the degree of gonadotoxicity, including radiation source, treatment field, total dose, and fractioning. Radiation induces gonadotoxic damage in a dose-dependent manner, and immature cells are more susceptible. A radiation dose <0.8 Gy may result in transient oligospermia, while higher doses more commonly cause transient azoospermia (0.8–2 Gy) or prolonged, at times irreversible, azoospermia (>2 Gy and >4 Gy) (Shalet, 1993). Much higher doses (20 Gy)

Table 1 Physiological fertility functions and possible mechanisms for temporary or permanent negative effect of cancer and its treatments

Fertility function	Tumor effect	Chemotherapy	Radiation	Surgery
Central GnRH, LH, FSH production	hCG produced by tumor	- There is no strong direct evidence to implicate chemotherapy as a cause of permanent dysfunction of the anterior pituitary - Androgen deprivation therapy suppresses the androgen hormonal axis	Cranial/brain radiation	Brain surgery
Spermatogenesis, sperm maturation, DNA compaction	- Testicular cancer associated with testicular development defects - Antisperm antibodies	- Spermatogonial stem cell damage - Direct damage to sperm DNA	Testicular radiation or scatter from abdominal/pelvic radiation	Unilateral or bilateral orchiectomy
Androgen production		- Higher doses than those needed to impair spermatogenesis may cause Leydig cell dysfunction and hypogonadism	- Higher doses than those needed to impair spermatogenesis may cause Leydig cell dysfunction and hypogonadism	Bilateral orchiectomy
Sexual response and erectile function	- Depression and loss of libido - Catabolic state	- Autonomic nerve damage that may result from chemotherapy with vincristine or platinum-based drugs can result in erectile dysfunction - Chemotherapy induced hypogonadism, especially due to alkylating agents, may result in sexual dysfunction - Systemic effects of chemotherapy (Fatigue, gastrointestinal, cutaneous, etc.) may also impair sexual function	- Pelvic radiation causing penile microvascular damage and erectile dysfunction - Brain radiation and loss of libido	- Spinal surgery - Pelvic surgery (e.g., radical prostatectomy, low anterior resection)
Ejaculation	- Direct local obstruction of vasa deferentia by tumor - Spinal or pelvic nerve involvement by tumor	- Autonomic nerve damage (see above) may also cause ejaculation disorder - Chemotherapy induced hypogonadism may result in low ejaculate volume	- May cause varied ejaculatory disorders: low ejaculate volume, anejaculation, discomfort during ejaculation, and hematospermia	- Pelvic surgery causing obstruction of vasa deferentia or pelvic nerve damage - Retroperitoneal or spinal surgery causing nerve damage

FSH, Follicular stimulating hormone; GnRH, Gonadotropin releasing hormone; hCG, Human chorionic gonadotropin; LH, Luteinizing hormone.

are required to impair Leydig cell activity, including testosterone production. The time needed for the recovery of sperm counts also depend on radiation dose. The use of fractionated radiation, often employed to reduce the toxic effect on healthy cells, is actually more harmful to spermatogenesis. Repetitive radiation doses damage reserve stem cells activated after the initial insult, resulting in significant spermatogenic injury and greater delay in spermatogenic recovery. Radiation may also interfere with fertility by impairing erectile function and ejaculation through microvascular damage to either spongiform tissue circulation or nerve supply. Finally, the extent of damage to the spermatogonial stem cells DNA from ionizing radiation is unclear, but may further jeopardize future fertility (Osterberg et al., 2014).

The Effects of Chemotherapy on Male Fertility

Similarly to radiation, chemotherapy targets proliferating cancer cells but is also detrimental to the rapidly dividing cells in the germinal epithelium. The cytotoxic agents penetrate the blood-testes barrier, damage the spermatogonial stem cells, disrupt spermatogonial differentiation, and may also directly damage sperm DNA. Leydig cells are much more resistant to chemotherapeutic insult, but at high doses Leydig cells injury and hypogonadism may ensue. The extent of the damage is largely dependent on the types of chemotherapeutic agents and their dose. It is generally accepted that alkylating agents, nitrogen mustard derivatives, and cisplatin are the most harmful drugs. On the other hand, antimetabolites such as methotrexate and mercaptopurine may cause

temporary suppression of spermatogenesis but are unlikely to have a lasting effect. Although higher doses of chemotherapy are more likely to cause persistent azoospermia, we are yet unable to predict gonadotoxicity severity for a specific individual, and post-therapy recovery of spermatogenesis remains unpredictable. Combination chemotherapies or the combination of chemotherapy and radiation are often employed in the management of various oncological diseases. The risk for prolonged or permanent azoospermia may vary significantly between treatment protocols. For example, different combinations given to Hodgkin's disease patients carry different risk: MOPP (mechlorethamine, oncovin, procarbazine, and prednisone) may result in azoospermia in 90% of patients up to 4 years after treatment and a high risk for permanent sterility, while ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) is associated with temporary azoospermia, generally resolving at 18 months. Sperm counts often decline in the first 6 months after the start of chemotherapy. Generally, age at time of chemotherapy is not a prognostic factor, and chemotherapy is equally damaging to spermatogenesis in children, adolescents, and adults. Sperm count recovery relies on the regeneration of stem-cell spermatogonia and may take up to 5 years.

The Effects of Surgery on Male Fertility

Surgery by itself can impair fertility, mainly through ejaculatory obstruction, ejaculatory dysfunction, or erectile dysfunction. The gonad itself may be removed by radical orchiectomy in testicular cancer. Furthermore, some testis cancer patients undergo retroperitoneal lymph node dissection, risking an injury to the sympathetic nerves and consequent retrograde ejaculation or anejaculation. While meticulous nerve sparing and modified template primary RPLND performed by a high-volume surgeon may reduce this risk to a minimum of 1%–5%, postchemotherapy RPLND is notoriously more difficult, with a risk of ejaculatory dysfunction up to 75%. Pelvic surgeries such as radical prostatectomy and radical cystectomy purposely disrupt the genital ducts (by cutting the vasa deferentia), and cause ejaculatory obstruction. Moreover, any radical pelvic surgery may cause erectile dysfunction via injury to the pelvic or cavernous nerves.

Table 2 summarizes the risks for infertility for different types of cancer treatments.

Fertility Preservation—What are the Needs

As the number of cancer survivors grow, it has become increasingly important to address quality of life issues in these patients. Cancer survivors experience numerous short and long term physiological and psychological sequelae of their cancer treatment. Among the possible consequences of cancer and its treatment in men are disruption of normal psychosexual development, erectile or ejaculatory dysfunction, and disruption of normal spermatogenesis. Future fertility and health of future biological children are considerable concerns for adolescents and young adults (AYA) cancer survivors, both before and after treatment. Despite their concerns, young cancer survivors often desire to sire biological children and wish to discuss reproduction and fertility preservation with their physician. Moreover, older men should not be assumed to have completed reproduction as more and more men become fathers at increasing age due to life choices or initiating a second family after a divorce or the death of a spouse.

Importantly, fertility preservation was shown to have an added psychological benefit. Two thirds of the patients that cryopreserved sperm reported drawing significant encouragement from the act. Many patients who did not bank sperm (and their caregivers) report regret and guilt. Nonetheless, implementation of patient education and fertility preservation counseling as a mainstay of oncological treatment was slow to occur. Information provided by health care professionals regarding risk of infertility and options for fertility preservation is often inadequate. Physicians may be disinclined to bring up the subject because of lack of knowledge, time constraints, or their own discomfort. Young patients (and caregivers) may have difficulties comprehending the potential implications, or may be too overwhelmed by their new diagnosis to address the subject. In a 2012 survey conducted by the LIVESTRONG foundation, only about a quarter of AYAs took steps to preserve their fertility before their cancer treatment began. Similarly, 30%–40% of patients report physicians did not discuss fertility issues with them prior to treatment, and only 50% were given the opportunity to bank sperm.

Over the past decade, there has been tremendous progress and substantial advocacy for fertility preservation. Aware of the barriers and difficulties, guidelines of a growing number of professional societies and organizations worldwide endorse early discussion of infertility risk with cancer patients and recommended sperm cryopreservation as a mean of fertility preservation in men. However, there is still room for improvement. A survey conducted among oncologists in 2009 revealed that < 25% of them reported to adhere to the ASCO guidelines for fertility preservation, and 50% have never discussed the risk of infertility or discussed it with less than a quarter of their patients (Quinn et al., 2009). Accordingly, a growing number of groups and organizations advocating for fertility preservation have emerged, providing education and support to cancer patients (see list of relevant web pages).

Strategies for Fertility Preservation

Currently, cryopreservation of sperm is the established method for fertility preservation in men. When needed, banked sperm can be thawed and used for assisted reproductive techniques (ART). The simplest way to acquire sperm is through masturbation and ejaculation. However, some patients are unable or unwilling to provide ejaculated semen specimen, and will require other form of

Table 2 Male infertility risk associated with cancer treatments

<i>Risk and duration of azoospermia</i>	<i>Radiation</i>	<i>Chemotherapy</i>	<i>Surgery</i>
High risk of prolonged or indefinite azoospermia	- Total body irradiation - Testicular radiation dose ≥ 6 Gy in boys, ≥ 1.2 Gy in adult males - Cranial/brain radiation ≥ 40 Gy	- Alkylating agents—as a single agent (Cyclophosphamide), or combination protocols (e.g., Procarbazine, Mustine, and/or Chlorambucil as in COPP, MOPP, or MVPP), or in combination with irradiation (e.g., Cyclophosphamide, Procarbazine, Chlorambucil) - Specific alkylating agents in prepubertal treatment (BCNU, CCNU) cause Azoospermia in adulthood - High dose alkylating agents for bone marrow transplant (e.g., containing Melphalan or cyclophosphamide $\pm$ busulfan) - Likely cause azoospermia (but always given with other gonadotoxic agents): Busulfan, Ifosfamide, BCNU, Nitrogen mustard, Actinomycin D	- Removal of both testicles - Removal of pituitary gland - Nonnerve-sparing RPLND
Intermediate risk, or azoospermia for 5 years	- Testicular radiation dose ~ 1 Gy (from scattering of abdominal/pelvic radiation)	- BEP (2–4 cycles) - Cisplatin - Carboplatin - Alkylating agents in lower doses combinations, e.g., cyclophosphamide in CHOP - Hormonal treatments (e.g., for prostate cancer)	- Removal of one testicle - Procedures within the pelvis (prostate, bladder, lower large intestine, rectum)
Low risk, or temporary reduction in sperm counts	- Testicular radiation dose 0.2–0.7 Gy	- Alkylating agents (dacarbazine, cyclophosphamide, and/or mustine) in lower-dose combinations, e.g., ABVD, OEPA, VACOP-B. - Nonalkylating combinations (e.g., VEEP) - Drugs that have a temporary effect alone but have an additive effect when combined with more gonadotoxic agents: Doxorubicin, Thiotepa, Cytosine arabinoside, Vinblastine, Vincristine. - Drugs that have a temporary effect, with a possible additive effect when combined with gonadotoxic agents: Amsacrine, Bleomycin, Dacarbazine, Daunorubicin, Epirubicin, Etoposide, Fudarabine, Fluorouracil, 6-Mercaptopurine, Methotrexate, Mitoxantrone, Thioguanine	- Nerve-sparing RPLND
No risk	- Testicular radiation dose < 0.2 Gy (from scattering) - Radioactive iodine	- Prednisone - Interferon-α	
Unknown risk		- Irinotecan - Oxaliplatin - Monoclonal antibodies (e.g., Bevacizumab, Cetuximab, Trastuzumab) - Tyrosine kinase inhibitors (e.g., Erlotinib, Imatinib) - Taxanes	

ABVD, Adriamycin (doxorubicin), bleomycin, vinblastine, and dacarbazine; BEP, Bleomycin, etoposide, and cisplatin; BCNU, Carmustine; CHOP, Cyclophosphamide, hydroxydaunomycin, oncovin, and prednisone; COPP, Cyclophosphamide, oncovin, procarbazine, and prednisone; CCNU, Lomustine; MOPP, Mechlorethamine, oncovin (vincristine), procarbazine, and prednisone; MVPP, Mustine, vinblastine, procarbazine and prednisone; OEPA, Oncovin, etoposide prednisone, and adriamycin (doxorubicin); RPLND, Retroperitoneal lymph node dissection; VACOP-B, Vinblastine, doxorubicin, prednisone, vincristine, cyclophosphamide, and bleomycin; VEEP, Vincristine, etoposide, epirubicin, and prednisone.

collection. Adolescents present a special challenge to banking sperm. There have been reports of sperm cryopreservation in adolescents as young as 11. However, the age of spermatogenesis is variable, and may be as late as age 15 years in normal males. Adolescents also present other challenges such as immaturity or inhibitions, and some may not have attempted self-stimulation previously. Several small cohorts report successful banking of sperm in 67%–83% of adolescents (Adank et al., 2014).

Collection of Ejaculated Sperm

The default method of sperm acquisition is through masturbation. Simply put, self-stimulation is inexpensive and safe, and usually provides sperm with the best quality. Sperm should be retrieved before gonadotoxic treatment is initiated. Optimally, the patient should abstain for 2–3 days before providing a semen sample. Occasionally, more than one sample is required to reach an adequate number of cryopreserved vials. The number of banked samples is variable, and depends on the quality of the semen sample, the degree of urgency in which treatment is advised, the andrology laboratory's protocol and experience, and the patient's desire. However, with current advances in ART, specifically intracytoplasmic sperm injection (ICSI), even one low quality ejaculate can yield sufficient sperm for conception of a biological child.

Some men are unwilling to produce a semen sample through masturbation. Several religions strictly disallow masturbation, not even in the context of fertility preservation. Possible solutions include the collection of postcoital semen or the use of a specially designed nonspermicidal perforated condom (allowed due to a tiny perforation at the end of the condom, which theoretically allows for some of the sperm to reach the partner while maintaining most of the sample in the condom), with the caveat being lower specimen quality. Other men will opt for medical solutions (designed for ejaculatory dysfunction) discussed in the next section.

Collection of Sperm From Patients With Ejaculatory Dysfunction

Patients who are unable to provide antegrade ejaculate through self-stimulation will require medical assistance to produce a semen sample. The different aetiologies of anejaculation and retrograde ejaculation, and a detailed description of treatment options such as penile vibratory stimulation (PVS) and electroejaculation (EEJ), are provided elsewhere. The suitable technique is decided according to the unique situation of the oncological patient. PVS is relatively simple and inexpensive, and can provide a good and quick solution for sperm acquisition with minimal delay of oncological treatment. Medical treatment with sympathomimetic agents for retrograde ejaculation is also simple but may require at least 36–48 h of treatment before providing a sample. Another treatment option for patients with retrograde ejaculation is the retrieval of sperm from a post-ejaculatory urine sample. EEJ necessitates more sophisticated and expensive equipment. It usually requires general anesthesia, and can be performed concomitantly with other procedures such as implanting a venous access device. Several small cohorts reported sperm retrieval rates of 48–68% in cancer patients, both adults and adolescents, undergoing EEJ prior to cancer treatment ([Adank et al., 2014](#); [Berookhim and Mulhall, 2014](#)). Eventually, if these methods fail to provide sperm, surgical extraction remains a viable option.

Collection of Sperm in Azoospermic Patients

Reported prevalence of azoospermia at presentation is variable, reported to range 1% to 15% in several large cohorts, contingent on cancer type. Azoospermic men will require some form of surgical retrieval of sperm. Uniquely, in azoospermic testis cancer patients a procedure to extract sperm can be performed concomitant with orchiectomy either *in vivo* or *ex vivo*. This procedure is referred to as “onco-TESE” (Oncological Testicular Sperm Extraction). Several authors described extracting sperm from the resected testis and, through ICSI, achieving pregnancies and live births of healthy children. A recent study found that the overall likelihood of presence of sperm in the tumor bearing testis is ~60%, suggesting that onco-TESE is a viable sperm extracting method ([Shoshany et al., 2016](#)). The importance of obtaining sperm through onco-TESE is underlined by the observation that up to 9% of men who have an apparently normal contralateral testis become azoospermic after orchiectomy. Onco-TESE was also performed successfully in azoospermic patients with other malignancies. TESE may also be an option in azoospermic cancer survivors who do not have banked sperm, as focal spermatogenesis is still possible if some spermatogonial stem cells survived the gonadotoxic treatment. A review of results from five centers found an overall sperm recovery rate of 44% in patients with azoospermia undergoing TESE after chemotherapy ([Picton et al., 2015](#)).

Cryopreservation of Sperm

Cryopreservation of sperm in cancer patients presents few unique challenges. Not infrequently, sperm produced by cancer patients at the time of diagnosis is of poor quality. In the process of cryopreservation, sperm parameters are further negatively affected. Motility may decrease by 25%–75% after thawing. Dilution with cryoprotectant reduces sperm concentration. Further detrimental effects have been suggested such as an increase of sperm DNA fragmentation and decondensation, as well as alterations of other sperm parameters that may be relevant for the fertilization process. Historically, with the use of slow freeze, approximately 50% of sperm survive the freezing process. Moreover, sperm from patients with certain types of cancer such as testicular cancer or leukemia show a markedly decreased survival after freezing ([Nangia et al., 2013](#)). Newer methods of cryopreservation, such as vitrification, are explored to improve post-thaw survival in samples of low sperm concentration. The reduced post-thaw quality may result in a need for a more demanding ART, as some patients who were intra-uterine insemination (IUI) candidates before cryopreservation, may require in-vitro fertilization (IVF) or ICSI when using their thawed banked sperm. At times, it may be difficult to find motile sperm in thawed specimens, possibly compromising ICSI outcome. Cryopreserved sperm can theoretically last indefinitely and reportedly used successfully after 28 years to conceive healthy offspring. The American society for reproductive medicine states

that caregivers should receive patient instructions on the handling of cryopreserved sperm in the case of patient death or unavailability ([Ethics Committee of American Society for Reproductive Medicine, 2013](#)). [Fig. 1](#) provides an algorithm for sperm banking and utilization.

Fecundity in Male Cancer Survivors

Overall Fecundity

Although many cancer survivors maintain their fertility, several studies show decreased fecundity in these men. The Childhood Cancer Survivor Study (CCSS) is a large cohort of five-year cancer survivors with various malignancies. One study reviewing male survivors reported that non-surgically sterile men were less likely to sire a pregnancy compared with their siblings, with a hazard ratio (HR) of 0.56 (95% CI – 0.49 to 0.63) ([Green et al., 2010](#)). Poor prognostic factors included radiation dose > 7.5 Gy to the testes, treatment with cyclophosphamide or procarbazine, and higher cumulative alkylating agents dose. However, patients with none of these risk factors did not have a significantly reduced likelihood of siring a pregnancy. A later review of the CCSS cohort ([Chow et al., 2016](#)), focused on a specific group of male survivors not treated with radiation, found an overall decrease in pregnancy rates (HR 0.63 [0.58–0.68]), which was also shown in men not exposed to alkylating or DNA interstrand cross-linking drugs (HR 0.72 [0.66–0.80]). A Norwegian cohort of similar magnitude studied childbearing in cancer survivors. Compared with age matched controls, postcancer births were 30% lower ([Cvancarova et al., 2009](#)). A large Finnish cohort of over 25,000 cancer survivors reported a 0.57 relative probability of having a first child ([Madanat et al., 2008](#)). Evidently, fecundity is lower in male cancer survivors, and some may require ART to conceive. As the return of spermatogenesis after chemotherapy or radiotherapy is unpredictable, it is uncertain who will need to use his cryopreserved sperm. Banked sperm may also be used in the post treatment time frame, in which there are significant risks for conceiving naturally (see “reproduction safety”). Although most studies suggest that only a minority (usually < 10%–15%) of men will use their stored specimens, for these men this may be the only way to sire a biological child.

ART Success Rate in Cancer Survivors

The advent of ICSI revolutionized the treatment of male infertility in general, and cancer survivors in particular, by allowing fertilization with virtually no lower limit on sperm quantity. Furthermore, ICSI was shown to achieve similar results with the use of fresh or cryopreserved sperm. Our knowledge of ART success in male cancer survivors is scarce and is based on small retrospective cohorts, mostly describing success with cryopreserved sperm. A recent systematic review reported on the use and effectiveness of sperm banking programs for cancer patients ([Ferrari et al., 2016](#)). A total of 30 studies were included. For IVF, the aggregated data analysis included 654 IVF cycles and showed a clinical pregnancy rate and a live birth or ongoing pregnancy rate per cycle of 30% and 25%, respectively. The cumulative rate of men achieving parenthood was 49%. These results are in line with IVF results in the general population. Retrospective cohorts comparing IVF results of cancer patients to other couples with male infertility also found similar success rates ([Garcia et al., 2015](#)).

Reproductive Safety in Men During and After Cancer Treatment

Concerns for reproductive safety are based on the potential mutagenic effects of cancer treatment. Both chemotherapy and radiation negatively impact DNA structure and stability. This DNA damage may theoretically have genetic implications for the offspring such as congenital malformations or cancer. Damage to sperm is short lived, as new sperm are constantly being produced. However, damage to the spermatogonial stem cells may incur a long lasting or permanent risk of implications on offspring. The harmful potential of cancer treatment is demonstrated through numerous studies reporting higher sperm aneuploidy rates, higher sperm DNA fragmentation and chromatin defects, as well as animal studies showing increased genetic translocations, mutations, and congenital malformations in offspring after exposure to chemotherapeutic agents. In addition, concerns regarding permanent changes to the epigenome have been raised recently. Researchers found that adolescents’ exposure to chemotherapy can permanently reprogram the spermatogenic stem cell epigenome with the potential to promote epigenetic inheritance to the next generation ([Shnorhavorian et al., 2017](#)). Recent ASCO recommendation state that men should be advised of a potentially higher risk of genetic damage in sperm collected after initiation of therapy ([Loren et al., 2013](#)).

Risk in the Immediate Posttreatment Timeframe

Two reproductive risks are to be considered in the immediate chemotherapy aftermath. First, a theoretical risk of the presence of chemotherapeutic agents in the ejaculate, being transmitted to the partner. Although it was estimated that the female’s expected blood exposure would be three orders of magnitude lower than the male’s total exposure, a potential risk cannot yet be ruled out ([Choy and Brannigan, 2013](#)). Second, studies have reported increased rates of sperm aneuploidy and DNA fragmentation to persist for up to 24 months after treatment ([Choy and Brannigan, 2013](#)). Currently, there is no consensus on the period considered safe for reproduction after cancer treatment. The only available guidelines are provided by the European Society for Medical Oncology. This group advocates deferral of childbearing for at least 12 months after cancer therapy, as a low-grade recommendation

Fig. 1 Fertility preservation counseling and management in male cancer patients. based on low level of evidence. Other researches recommend an extended period of 18–24 months, especially in patients who became azoospermic, indicating the spermatogonial stem cells may have been affected (Agarwal et al., 2014; Nangia et al., 2013).

Risk in Natural Conception

So far, most studies on children born to men with a history of cancer were reassuring (Ethics Committee of American Society for Reproductive Medicine, 2013; Lee et al., 2006). Unlike children born to female cancer survivors, offspring of male cancer survivors did not show a significant increased obstetric risk, perinatal morbidity, or decreased birth weight (Nagarajan and Robison, 2005). Several studies reported that the risk for congenital abnormalities was comparable to that of children of noncancer population. However, a recent large study from Danish and Swedish registries of over 1.77 million children reported conflicting results (Stahl et al., 2011). The authors found an increased overall risk of major congenital abnormalities in offspring of male cancer survivors (RR = 1.17; 95% CI 1.05–1.31). It is possible that studies to date were not sufficiently powered, and the conflicting results calls for further research.

Risk in ART

There are no good quality studies reporting on reproductive safety in male cancer patients utilizing ART. Two small cohorts reporting on ART success in male cancer patients reported the birth of 37 and 20 children, and all children were reportedly healthy with no congenital malformations or childhood malignancies (Chan et al., 2001; Ping et al., 2014). The aforementioned Danish and Swedish registries study (Stahl et al., 2011) found that the risk of congenital abnormalities was not modified by the mode of conception (natural vs. ART). Furthermore, a similar prevalence of major congenital abnormalities was observed in children born using fresh post-treatment sperm and those conceived using cryopreserved pre-treatment sperm. Up until now, the literature suggests that children born following IVF/ICSI have only modestly increased risk of most malformations, cancers, and birth defects and no evidence of impaired psychosocial development (Ethics Committee of American Society for Reproductive Medicine, 2013). It is still debatable if those risks are conferred by the ART technique, or are the manifestation of the genetic makeup of parents with subfertility or over diagnosis due to a more stringent follow up. However, other risks should be considered such as increased risk for multiple births and increased risk of perinatal problems such as low birth weight, prematurity, and perinatal mortality (Ethics Committee of American Society for Reproductive Medicine, 2013). Some cancer survivors will resolve to use their pretreatment cryopreserved sperm. In general, there is no evidence of an increased risk of adverse outcomes if cryopreserved rather than fresh sperm are used for ART.

Risk of Cancer in the Offspring

In the absence of a heritable cancer syndrome there does not appear to be an increased prevalence of malignancies in children born to men treated for cancer (Lee et al., 2006; Madanat-Harjuoja et al., 2010). The American Society of Clinical Oncology guidelines recommend that men should be advised of a possible, not yet quantifiable, higher risk of genetic damage in sperm of men with cancer or that underwent cancer treatment (Lee et al., 2006). A possible higher risk of cancer in the offspring conferred by ART is a contested subject, but should also be considered. Men who have a heritable genetic form of cancer with a known mutation may wish to use PGD or prenatal diagnosis to reduce the risk of the birth of a child with a similar disorder.

Future Perspectives

Worldwide, great effort has been made by the scientific community to try and develop new methods to preserve or reconstitute fertility, particularly in prepubertal patients who cannot cryopreserve sperm. Currently, there are no established clinical methods to achieve this goal. It is estimated that each year in the US alone there are >4000 prepubertal males facing cancer treatment and unable to cryopreserve sperm. A growing number of institutions are now offering these patients to cryopreserve testicular tissue or cell suspensions, with the hope that one of the currently experimental techniques will mature and be clinically available in the near future. These technologies include manipulation of spermatogonial stem cells in order to transplant them back into the testis or to grow mature sperm ex vivo, manipulation of testicular tissue via grafting (autologous or xenograft) or organ culture, induction of pluripotent stem cells to mature into germ cells, and gene therapy (Gassei and Orwig, 2016). These experimental technologies are fraught with technical and ethical obstacles, as well as safety concerns such as re-introducing malignant cells to the patient, transmission of zoonotic viruses, and risk for the offspring's genetic health (Gassei and Orwig, 2016).

PVSA Post vasectomy semen analysis

Introduction

Surgical sterilization has always been a reliable option for contraception in both men and women. Vasectomy is an outpatient procedure performed by most practicing urologists and select general practitioners. An estimated 350,000 procedures were performed in the United States in the year 2002 according to data extrapolated from National Survey of Family Growth ([Eisenberg and Lipshultz, 2010](#)), and a physician survey placed the incidence at over 526,000 per year ([Barone et al., 2006](#)). Vasectomy ranks as one of the most cost effective means of contraception, with the cost of approximately \$400–\$700 for patients in the United States ([Trussell et al., 2009](#)). Yet, despite comparable efficacy and its minimally invasive nature, vasectomy trails behind its female counterpart, tubal ligation. Trends in Contraceptive Use 2015, a data set published by the United Nations, revealed that male sterilization accounts for a mere 2.4% when compared to a prevalence of 19.2% for female sterilization ([United Nations, Department of Economic and Social Affairs, Population Division, 2015](#)). In fact, with the exception of northern Europe and Canada, vasectomy represents a small fraction of surgical sterilization performed.

History

Cooper performed the first documented vasectomy on a dog in 1823, but the first vasectomy performed on a human is less certain, although some credited R. Harrison, who completed the procedure in hopes of achieving prostate atrophy ([Leavesley, 1980](#)). In the ensuing period of late 19th and early 20th century, forced male sterilization played a part in the eugenical sterilization policy with passage of statutes in 12 states in the United States. Over 1400 sterilizations of institutionalized persons were performed between 1907 and 1917, as a means of “preventing the spread of defected germ plasm.” These laws were ultimately overturned in 1918 ([Reilly, 1983](#)). It was not until the time of World War II that vasectomy was regarded as a form of birth control.

Perioperative Considerations

Factors Influencing the Choice of Vasectomy

Numerous factors influence the selection of surgical contraception. Interestingly, a study performed on married couples seeking sterilization revealed that while the decision making process is shared between the couple, the final model entailed predominantly wife-only variables. This emphasizes the significance of spousal influence on men seeking and ultimately undergoing vasectomies ([Miller et al., 1991](#)). In the United States, men who are of non-Hispanic ethnicity and who have visited family planning clinics were more likely to select vasectomy. On the other hand, men with a lower education level were more likely to report their partners as undergoing tubal ligations ([Anderson et al., 2010](#)). The latter phenomenon is likely a reflection of the model of health care in the United States; the author of the study postulated that higher rates of tubal ligation in women of lower socioeconomic status may be related to the Medicaid coverage for sterilization in the post-partum period.

Preoperative anxiety certainly exists as one of the barriers to vasectomy. A study has shown that a group of men seeking vasectomy displayed a mean anxiety level of 3.5 out of a 10 point scale, where the most common reasons for anxiety were anticipated pain (27%) and fear of the unknown (23%) ([Sandlow et al., 2001](#)). The most prominent reason compelling men to select vasectomy over their partner obtaining tubal sterilization is because it is safer and simpler, reported by 62% of the men surveyed. An

additional 14% stated that it was their turn to shoulder the responsibility for contraception, and 22% cited that their partners disliked other contraceptive measures (Barone et al., 2004).

Preoperative Counseling and Evaluation

Preoperative counseling and evaluation is an important component of planning prior to surgical sterilization. The minimum age of requirement for vasectomy is usually 18 years matching that of age of consent, but this may vary depending on the country, state, or jurisdiction involved. While the majority of men seeking vasectomy reports a straight forward decision making process, up to 45% of men felt that the decision was a difficult one (Balde et al., 2006). As such, the clinician is obligated to schedule a consultation session to adequately address the patient's concerns and to discuss the necessary and minimum concepts associated with surgical contraception. Ideally a face to face encounter, the consultation may also utilize telephone or even electronic methods of communication that involves a two-way flow of information. The physical examination, with emphasis on the genitourinary system, may also be deferred to the day of the procedure. It may also be prudent to have the patient's partner present during the preoperative appointment but this is not a requirement. According to the American Urological Association, the patient should be made aware of the following concepts included in Table 1 (Sharlip et al., 2012). The above list constitutes the bare minimum points of discussion prior to vasectomy, but there are certainly additional non-essential, but nevertheless, important factors that may require dialog. These are covered in detail in the AUA guidelines on Vasectomy.

Surgical Procedure

Surgical Approach and Mechanism of Sterility

As mentioned prior, vasectomy is usually an outpatient procedure, most often performed in the office setting. Two surgical steps are important: vasal isolation and vasal occlusion. Prior to vas isolation, local anesthesia consistent of lidocaine and bupivacaine is administered intradermally followed by deeper infiltration to the perivasal sheath, which contains abundant neurovascular tissue (Fig. 1). Adjunctive topical anesthetics such as creams or sprays may be employed, but the evidence on their efficacy remains conflicting. Oral or intravenous anxiolytics may be used for patients who report a high level of pre-procedural anxiety. Rarely, general anesthesia or conscious sedation are reserved for patients who have unfavorable anatomy or simply cannot tolerate the discomforts of the procedure.

Conventional vasectomy (CV) was the most practiced technique prior to the introduction of minimally invasive instruments and their associated surgical refinements. CV is performed by making one midline scrotal incision or bilateral scrotal incisions using a scalpel. Incisions usually measure between 1.5 and 3.0 cm and the vas deferens is exteriorized using a surgical clamp.

Minimally invasive vasectomy (MIV) was developed in recent years and facilitated by the advent of specialized instrumentation. MIV has the following defining characteristics: (1) incisions/openings in the scrotal skin that measure ≤ 10 mm, either as a singular midline scrotal opening or bilateral openings and (2) minimal dissection of the vas and perivasal tissue. Single versus bilateral incisions usually depend on physician preference and influenced by patient anatomy. The use of a single opening or incision may reduce procedure time and the incidence of adverse events, but a large observational study examining 1800 patients did not perform statistical testing (Castillo Jimeno et al., 1992). In general, the single incision vasectomy localizes the surgical opening to the midline just below the penoscrotal junction (or halfway between the junction and the top of the testes) whereas the bilateral approach places the incision at the level of the penoscrotal junction. Experts recommend these surgical sites to aid in the isolation of the straight portion of the vas deferens. Moreover, for the single opening vasectomy, the surgeon has to ensure that the same vas is not isolated and occluded in two locations, while leaving the contralateral vas unoccluded.

As a form of MIV, the no-scalpel vasectomy (NSV) was developed in 1974 in China by Dr. Li Shunqiang and has since gained worldwide acceptance. The seminal publication by Li et al. describes the procedure in detail (Li et al., 1991), but a brief description of the procedure will be included here. NSV makes use of the vas ring clamp to isolate the vas, perivasal tissue, and overlying skin (Fig. 2). A small defect is then created in the skin with the vas dissector, measuring < 10 mm, and the anterior vasal sheath is spread

Table 1 AUA guidelines—minimum and necessary concepts to be discussed during a preoperative evaluation for vasectomy

Necessary concepts

1. Vasectomy as a method of contraception is considered permanent
2. It does not produce immediate sterility and so family planning is necessary until vasal occlusion is confirmed
3. Vasectomy is not 100% reliable. The failure rate associated with vasectomy is approximately 1 in 2000
4. Repeat vasectomy is necessary in $< 1\%$ of vasectomies provided that a technique known to have low failure rate has been used
5. The patient should refrain from sexual intercourse or ejaculation for 3–7 days
6. There are options for fertility after vasectomy but they tend to be expensive and have lower rates of success
7. As with all surgeries, there are risks of bleeding and infection
8. There is risk of chronic pain after vasectomy
9. There are alternatives, both permanent and non-permanent

Fig. 1 Administration of local anesthetic.

open (**Fig. 3**). The vas deferens is then isolated and elevated from the skin opening using a supination maneuver and re-purchased using the ring clamp. The residual posterior sheath tissue, containing much of the neurovascular contents, is then dissected off. Vasal occlusion in the form of division, with or without segmental excision, is performed last.

The mechanism of sterility in vasectomy is vasal occlusion, the blockage of the flow of sperm through the lumen of the vas deferens. This can be achieved through several different techniques, most involving the division and/or excision of a segment of the vas. The only method of vas occlusion without division is the extended electrocautery, or Marie Stopes International technique, but it is rarely used in the United States. This method in particular employs full thickness electrocoagulation of the anterior vasal wall with a partial thickness coagulation of the posterior wall, for a length of approximately 2.5–3 cm ([Black et al., 1989](#)). Failure rate after this technique is comparable to other methods of vas occlusion, as demonstrated retrospective study with over 41,000 patients, and a reoperation rate of 0.46%–0.7% ([Black and Francome, 2002](#)).

There are several techniques of vasal occlusion employed after division of the vas. Commonly, the vas ends may be occluded with ligature or clips (**Fig. 4**). Thermal energy may also be applied to the luminal mucosa to achieve occlusion. Fascial interposition (FI), which is the suturing of the internal spermatic fascia to intervene between the divided vas ends, serves to prevent possible recanalization, and may be used in tandem with the above occlusive techniques. A notable variation is the open ended vasectomy, where the testicular end of the severed vas is left unoccluded. The intended benefit of this technique is to reduce the risk of post vasectomy pain by decreasing the back pressure in the epididymis. The open ended technique may also facilitate the formulation of sperm granuloma at the transected end of the vas ([Shapiro and Silber, 1979](#)). When the open ended technique is used, FI is

Fig. 2 Isolation of the vas during a no-scalpel vasectomy.

Fig. 3 Dissection during the no-scalpel vasectomy.

indicated to reduce the likelihood of recanalization. Additionally, some practitioners also excise a short segment of the divided vas, but the AUA expert panel found no convincing evidence to support the superiority of division/excision over division alone ([Sharlip et al., 2012](#)).

The AUA guidelines found that mucosal cautery with or without FI has the lowest failure rate.

Post-operative Considerations

Post Vasectomy Semen Analysis

A post vasectomy semen analysis (PVSA) is obtained to document the clearance of motile sperm before the man can rely on vasectomy alone for contraception. There is substantial variability in the time period required for the clearance of sperm, a process that is seemingly affected by anatomy, age, and possibly the number of ejaculations post vasectomy. Non-motile sperm may persist in the ejaculate for months after vasectomy ([Arango Toro et al., 1993](#)), and this may be due to the presence of residual sperm in the seminal vesicles, ampulla of the vasa and/or micro recanalization ([Freund and Couture, 1982](#)). Persistent motile sperm in the PVSA is concerning, and it prompts careful follow up. It may be caused by the erroneous double occlusion of the same vas deferens or early re-canalization. In most cases, however, semen samples provided 3 months after vasectomy have either no sperm or a small number of non-motile sperm. From a laboratory standpoint, PVSA should be conducted without centrifugation of the

Fig. 4 Division of the vas and ligation of the two ends.

sample. Despite previous society guidelines that supported the use of routine centrifugation of azospermic semen samples, a recent study has shown that uncentrifuged semen analysis retains a sensitivity of 99.3% and negative predictive value of 99.8% for identifying samples with $\leq 100,000$ sperm/mL (World Health Organization, 2010; Hancock et al., 2002; Steward et al., 2008). The use of centrifuged specimen may detect the presence of sperm without clinical significance and prompt unnecessary testing or repeat vasectomies (Sharlip et al., 2012). According to the AUA, a PVSA should be performed 8–16 weeks post procedure and the patient may stop using other family planning measures when one uncentrifuged fresh specimen reveals azoospermia or rare non-motile sperm ($\leq 100,000$ sperm/mL) (Sharlip et al., 2012; Chawla et al., 2004).

Failure of vasal occlusion likely occurred should motile sperm persist 3–4 months after vasectomy. Repeat PVSA's are recommended until 6 month post vasectomy because up to half of the men with detected motile sperm ultimately achieve delayed vasectomy success (Labrecque et al., 2005). The physiologic process of both recanalization versus delayed success have not been completely elucidated, but may be related to post vasectomy inflammatory process and fibrosis.

Complications/Adverse Sequelae

The rate of complications following vasectomy is quite low. As with all surgical procedures, vasectomy carries with it risks of infection, bleeding, and damage to adjacent tissues. Bleeding, along with the formation of a scrotal hematoma, is a well-known risk of risk of vasectomy and has been estimated to 1%–2% in most series (de los Rios Osorio and Castro Alvarez, 2003; Kumar et al., 1999; Rees, 1973). Surgical site infection is rare and current recommendations do not support the use of perioperative antibiotics unless the patient falls into the high risk category, such as diabetes or an immunocompromised state. Chronic scrotal pain can manifest after vasectomy, presenting as a detriment to the overall quality of life. A retrospective cohort study compared men who had undergone vasectomy to non-vasectomized controls found that 6% of cases versus 2% of controls reported scrotal pain of sufficient bother that medical advice was sought. Notably, none of the individuals who elected for vasectomy later regretted their decision (Morris et al., 2002). In a well-designed prospective study, 593 respondents were surveyed before and after vasectomy. New onset scrotal pain was detected in 14.7% of the men approximately 7-month post vasectomy with a mean visual analog score of 3.4/10. Most importantly, four men (0.9%) reported pain that was quite severe and adversely affecting their quality of life (Leslie et al., 2007). Given the relative difficulty of studying post vasectomy orchalgia and the limited number of well-designed prospective studies, the AUA expert panel has reviewed available data to estimate the incidence of chronic scrotal pain severe enough to affect quality of life at 1%–2% (Sharlip et al., 2012).

Long-Term Risks

Multiple retrospective studies were performed to evaluate the possible linkage between vasectomy and coronary heart disease, hypertension, strokes, but the summary body of evidence does not point to any association (Beaglehole et al., 1985; Chi et al., 1990; Rosenberg et al., 1986; Tang et al., 1988; Massey et al., 1984). A limited number of studies actually suggest that men who had undergone vasectomy reported better states of health compared to their counterparts.

Primary progressive aphasia (PPA) is a language based dementia, fitting under the broader category of frontotemporal degeneration. One case control study was prompted by the report of a 43-year-old male who reported progressive word finding difficulty, correlating his onset of symptoms in the post vasectomy period. The authors compared 47 men with PPA to 57 men with no cognitive impairment and found that the age adjusted rate of vasectomy was significantly higher (40% vs. 16%, $P = 0.02$). Their hypothesis is that antisperm antibodies (ASA) that are produced after vasectomy may share antigenic epitopes with the brain, triggering an immunologic response akin to a paraneoplastic process (Weintraub et al., 2006). Interestingly the study did not measure the levels of ASA between case and controls, which would have certainly bolstered their hypothesis. A later study conducted in patients with Alzheimer's disease did not detect an association between the presence of ASA and cognitive function (Han et al., 2010). One must keep in mind that even if an association exists, the causality cannot be proven in a retrospective fashion.

From an oncologic perspective, meta-analysis of available data failed to demonstrate an association between vasectomy and testicular cancer (Sharlip et al., 2012). The AUA also performed an exhaustive review of available literature published on the correlation between vasectomy and prostate cancer. Over 30 studies spanning several decades were evaluated and the overwhelming negative findings lead the panel to conclude that vasectomy does not predispose men to develop clinically significant prostate cancer. Since the publication of the panel recommendations, additional research has been conducted on this subject. Nayan et al. published a large scale matched cohort study, which included over 320,000 men who had undergone a vasectomy matched 1:1 with men who did not. Some 3400 cases of prostate cancer were identified, and after adjustment for measures of health seeking behavior, no association was found (HR 1.02, 95% CI 0.95–1.09) (Nayan et al., 2016). Research originating from the United States also affirmed the above findings; among the Cancer Prevention Study II cohort of over 360,000 men, no association was found between vasectomy and prostate cancer mortality (Jacobs et al., 2016).

Future Directions

There remains a number of topics related to vasectomy that warrants further research. Certainly the basic science of the immunologic cascade after surgical sterilization remains to be elucidated. While numerous technical advances have been made in the recent

decades, surgeons should still strive for continued refinement, in the hopes of reducing patient discomfort and post-operative complications. Perhaps even more important, providers should focus on the areas of patient education, counseling, and general dissemination of vasectomy as a viable, safe, and reliable method of contraception. Rectifying the relative under-utilization of male sterilization will not only benefit men and their partners, but it may also deliver cost savings for health care system.

Penile Prosthesis for Erectile Dysfunction

Culley C Carson, University of North Carolina, Chapel Hill, NC, United States

© 2018 Elsevier Inc. All rights reserved.

While erectile dysfunction (ED) has plagued men since ancient times, effective treatment has only been available since the late 20th century. The era of implantable devices for ED began with the development of silicone-based prosthetic materials in the late 1960s (Carson, 2005). Modern penile prosthetic devices were first developed in the early 1970s when Small et al. (Small et al., 1975) along with Scott et al. (Scott et al., 1973) reported the implantation of penile prosthetic devices into the corpora cavernosa to fill the corpora cavernosa and provide a physiologically functional erection with good cosmetic results. These devices have undergone revisions and redesigns between the early prosthetic devices and the currently implanted inflatable penile prostheses. Current inflatable prosthetic devices have improved mechanical reliability and reduced infection risk. These current devices can be divided into semirigid and multiple-component inflatable penile prostheses of which there are two- and three-piece models available. (See Table 1.)

Semirigid rod available today are the successors of the devices designed in the 1970s. These devices, while easier to implant, have few advantages over the newer inflatable devices because infection and mechanical malfunction rates are similar. The semirigid devices usually consist of a central metal core and a silicone elastomer rod a series of disks held in position by a central cable. The latter design facilitates positioning of the implant between uses. The overwhelming preference in the United States is for the three piece inflatable implant.

The three-piece inflatable penile prostheses vary in construction from three-layer silicon/Dacron/Lycra/silicone to a single layer of silicon or Bioflex. Options include girth expansion and/or length elongation in the AMS 700 LGX device. Device structural modifications have decreased mechanical malfunction rates from greater than 30% to less than 5%. The most significant recent advance is the coating of three-piece implants to reduce infection risk.

The three-piece inflatable penile prostheses continue to be the most satisfactory prostheses once they are implanted. These prosthetic devices produce the most natural appearing erection in girth, length, and with satisfactory rigidity and excellent flaccidity for optimal concealment. They also have advantages for many patients with complex penile implantations because the flaccid position removes pressure from the corpora cavernosa and decreases the possibility of erosion in these complex patients.

To improve ease of surgical implantation and remove a portion of the prosthesis placed within the abdominal region, two-piece prostheses were designed. Because these two-piece inflatable prostheses remove the separate reservoir, additional fluid is available either by a larger scrotal pump or a combination of proximal cylinder and pump reservoir. Although these devices provide adequate erection in many patients, the limited reservoir capacity decreases flaccidity and may, in some patients, diminish rigidity. These prostheses are especially difficult to deflate in patients with small penises and frequently provide inadequate rigidity of patients with longer penises. While less optimal than three-piece devices, these two-piece implants may be acceptable for patients in whom reservoir placement is difficult or contraindicated. Such patients as renal transplant recipients and patients who have undergone significant radical pelvic exenteration procedures may benefit from two-piece devices.

Diagnosis of ED

The diagnosis of erectile dysfunction can be obtained by history (Montorsi et al., 2010). The clinician should determine whether the erectile dysfunction is situational or constant, whether the degree of dysfunction is partial or total, and also include the details of the relationship with the partner. Any coexisting conditions such as diabetes, vascular disease, smoking, medications (especially steroids, hormones, antihypertensives, or antidepressants), and use of alcohol or drugs should be identified. Physical examination should include the genitalia including the testes, hair distribution, femoral and distal lower-extremity pulses, and the penis for Peyronie's plaques or other abnormalities.

Indications

While there are several penile prosthesis designs available for implantation, not all patients with ED are candidates for penile prosthesis implantation. Penile prostheses are generally a procedure of last resort for those men failing more conservative measures such

Table 1 Available penile prostheses

<i>Semirigid Rods</i>	<i>Inflatable</i>
AMS 600 (AMS)	<i>Three piece</i> 700 CX (AMS) 700 LGX(AMS)
Malleable (Coloplast)	Alpha 1 (Coloplast)
Dura II (AMS)	<i>Two piece</i> Ambicor (AMS)

as oral PDE5 inhibitors, vacuum erection and cavernosal injection therapy (Hellstrom et al., 2010). For those men in whom penile prostheses are suggested, careful counseling with the patient and his partner before penile implant procedures will limit many of the problems with postoperative dissatisfaction. Once the discussion and demonstration of penile implant varieties has been carried out, patients can be counseled about the most appropriate penile prosthesis. Patients may choose a specific prosthetic type based on their needs and preferences (Hellstrom et al., 2010). Younger patients with normal manual dexterity and patients who wear stylish, form-fitting, athletic clothing or who shower in public at a health club often choose a three-piece inflatable penile prosthesis because appearance in the flaccid position is better than other designs. Similarly, patients with Peyronie's disease, secondary implantation, or significant peripheral neuropathy such as occurs in severe diabetes are best served with an inflatable penile prosthesis because interior tissue pressures are diminished between uses and the possibility of extrusion is diminished.

For patients in whom the convenience of inflation and deflation are not important, the risks and mechanical malfunctions may outweigh the disadvantage of a malleable penile prosthesis. Such patients as paraplegics who require external urinary collection device, men with inadequate manual dexterity, or those with significant obesity may be better served with a malleable penile prosthesis.

Surgical Approach

Surgical implantation of penile prostheses can be carried out using a variety of surgical approaches and incisions. Semirigid and malleable prostheses can be implanted through a distal penile approach. Multiple-piece prostheses, however, can be implanted by the infrapubic or penoscrotal approach. While individual surgeons have a variety of rationales for each of these approaches, there does not appear to be any clear advantage in patient satisfaction or outcome of the two approaches. Patient anatomy may dictate appropriate choice. Patients with previous abdominal surgical procedures where reservoir placement is difficult may be better served with an infrapubic approach while patients with massive obesity may be better approached through a penoscrotal incision. Two-piece devices, because there is no separate reservoir, are best implanted through a penoscrotal incision.

A distal penile approach is usually the best approach for insertion of a semirigid or mechanical penile prosthesis. This incision heals well, allows complete corporeal dilation, and facilitates rod placement.

The infrapubic approach allows better visualization of the three piece prosthesis reservoir placement than the penoscrotal approach. However, because of the proximity of the dorsal neurovascular bundle in the infrapubic approach, injury is possible, resulting in decreased distal penile sensation in some patients. The infrapubic approach is usually carried out with a horizontal incision approximately one finger breadth below the symphysis pubis, allowing implantation with an easily concealed incision once the pubic hair regrows. In patients with significant obesity or a previous midline incision, however, a midline incision can be used.

Three-piece inflatable penile prostheses, as well as, semirigid and two-piece prostheses can be implanted by a transverse or vertical penoscrotal incision. This approach has distinct advantages in obese patients and is the most common approach for routine three piece penile prosthesis implantation. In men with a penoscrotal skin web, the horizontal skin incision can be closed in a midline fashion to enhance functional penile length.

Perioperative antibiotic treatment is critical in diminishing incidence of perioperative infection and prosthetic removal. The Inhibizone (American Medical Systems, Minnetonka, MN) coating consisting of rifampin and minocycline or the lubricious coating of the Titan implant (Coloplast Inc., Minneapolis, MN) which allows antibiotics to adhere to the bioflex have reduced infection risk by 3 fold. An initial perioperative dosage of an antibiotic agent effective against the most common infectious pathogens should be administered 1–2 h prior to surgery and continued for 24 h postoperatively. Surgical guidelines suggest a choice of an aminoglycoside with a first-generation cephalosporin, ampicillin/sulbactam a cephalosporin alone, vancomycin, or a fluoroquinolone is appropriate for prophylaxis of the most common infections from *Staphylococcus epidermidis* (Hellstrom et al., 2010). The use of antibiotic-coated penile implants, while reducing the incidence of postoperative infection, does not preclude the need for systemic, perioperative antibiotics. The penile prosthesis remains deflated for 4 weeks while healing occurs. Prior to activation, the patient is advised to retract the pump into his scrotum on a daily basis and tight underwear and athletic supports are avoided to maintain pump position. A return clinic visit for activation of the device is carried out once discomfort has resolved. Patients are advised to inflate and deflate the device on a daily basis for 10–12 weeks to allow tissue expansion around the prosthesis. Most patients can then begin use of their device 4–6 weeks after implantation.

Complications

Despite careful counseling, many patients enter penile prosthesis procedures with expectations that cannot be met by penile prosthesis surgery. Complaints about decreased penile length compared with preimplant state, decreased penile sensation, "coolness" of the penis and glans penis, and chronic pain, as well as partner dissatisfaction, are among the complaints patients may voice despite adequate surgical implantation and satisfactory mechanical functioning. Fortunately, these complaints are unusual and more than 90% of patients report satisfaction with their prostheses (Carson, 2003). Many patients who are dissatisfied with their penile prostheses will benefit from sexual counseling or continued counseling assistance from the implanting surgeon to be sure that they are able to operate the device satisfactorily and understand its use.

Most patient's dissatisfaction results from difficulty with operation of the device and unrealistic expectations. Preoperative discussions with patients should include the concept that penile prostheses do not create normal erections but only support the penis for sexual activity. Penile prosthesis surgery brings about the ability to resume sexual functioning and vaginal penetration, but decreased penile sensation, length, and engorgement may result. Patients should also be advised that a penile prosthesis will not improve libido or ejaculation. Patients frequently report delayed or difficult ejaculation initially following penile prosthesis surgery. This delay is primarily a result of inadequate preparation, stimulation, and psychological adjustment to the prosthesis. Most patients require 3–6 months of prosthesis use with careful attention to presexual stimulation before ejaculation routinely returns to preoperative levels. Because the prosthesis neither improves nor detracts from preoperative ejaculatory ability, patients must be counseled regarding their preoperative ejaculatory ability before prosthesis placement.

The most worrisome postoperative complication is infection, which occurs in fewer than 10% of all patients (Carson et al., 2000). Perioperative prosthetic infections can, however, occur at any time in the postoperative period in patients with penile or other prosthetic devices. Patients continue to be at risk for hematogenously seeded infections from gastrointestinal, dental, or urologic manipulations as well as remote infections. Patients must be counseled to request antibiotic coverage if remote infections occur. Most periprosthetic infections are caused by Gram-positive organisms such as *S. epidermidis*, but fungi or Gram-negative organisms such as *Escherichia coli* and *Pseudomonas* are also common culprits. Severe gangrenous infections with a combination of Gram-negative and anaerobic organisms have also been identified and frequently result in significant disability and tissue loss. Patients at increased risk for perioperative infections include diabetics, patients undergoing penile straightening procedures or circumcision with prosthetic implantation, patients with urinary tract bacterial colonization, and immunocompromised patients, such as posttransplant patients. Spinal cord injury patients have also been reported to have a specially increased risk of infections, with rates reported as high as 15%.

Appropriate treatment of periprosthetic infections requires early and immediate identification with institution of parenteral antibiotic therapy and early prosthesis removal (Carson, 2003). Conservative treatment would dictate a healing period of 3–6 months followed by repeat prosthesis implantation. Satisfactory results with prosthesis removal, a 5–7 day course of antibiotic irrigation, followed by additional replacement has been reported for selected patients. Better long-term results with no additional morbidity can be achieved with the prosthesis salvage technique reported by Mulcahy (Carson, 2003). This technique—which requires removal of the infected implant and vigorous irrigation using solutions of antibiotics, provadone iodine, hydrogen peroxide, and a repeat of these solutions—is successful in more than 75% of infected prostheses (Carson, 2003).

The most common complication of penile prosthesis function is mechanical malfunction. Mechanical malfunction has declined from rates as high as 61% to levels below 5% since the 1970s (Scott et al., 1973; Carson, 2003). Aneurismal dilation of inflatable cylinders, both American Medical Systems and Mentor, tubing kinking, reservoir leakage, and pump malfunction have been limited by device modifications. Fluid leak, however, continues to be a problem for many inflatable penile prostheses. These mechanical malfunctions require replacement of the leaking portion of the inflatable portion of the prosthesis. If a nonfunctioning prosthesis has been in place more than 4 years, however, it is usual practice to replace the entire device to reduce further mechanical malfunction (Hellstrom et al., 2010).

Semirigid rod penile prostheses are associated with fewer mechanical problems; the most common complication associated with these prostheses is cylinder erosion through skin or urethra. Prosthesis fracture or breakage has been reported and patients may return 6–8 years postimplantation with complaints of decreased rigidity of their semirigid rod, indicating fracture of central prosthetic cylinder wires. These wire fractures cannot usually be appreciated radiographically unless the prosthesis is put on stretch once it has been explanted. Replacement of these devices is indicated when patients note decreased rigidity. Prosthesis extrusion or erosion is most common in diabetics and spinal cord injury patients, especially those requiring urinary management with catheter placement or of condom catheter collection devices.

Extrusion can also occur beneath the penile skin distally from vigorous dilation or remotely from trauma or repeated use. These extrusions are characterized by distal penile pain with use. Correction can be carried out with the use of a patch graft, but a better approach is rerouting with no grafting material. Rerouting is associated with less infection and pain and a reduced recurrence rate.

Results

Long term function and use have been confirmed in studies of patients with implants as long as 10 years (Hellstrom et al., 2010; Carson et al., 2000). While partner satisfaction literature is sparse, patients have a greater than 90% satisfaction and those with functioning devices for more than 5 years used them 27 times monthly (Carson et al., 2000). Other studies have confirmed that patient satisfaction is greater than any other ED treatment modality (Carson, 2005).

Glossary

Angioplasty An endovascular treatment specific to artery while balloon tamponade and arterial stent are always used in one setting.

Deep dorsal vein arterialization A hybrid surgery for erection restoration by increasing penile arterial supply using donor artery and meanwhile the circumflex veins were ligated to limit the venous drainage.

Electrocautery A device can deliver electrical energy to coagulate vascular lumen and prevent the blood vessels from bleeding.

Erectile dysfunction A newer term to replace the older one impotence which is defined as inability either to attain or maintain a rigid erection for satisfactory coitus.

Penile arterial insufficiency A situation that penile supply artery is dysfunctional. The supplying artery fails to adequately feed the sinusoidal tissue, in turn, unable to attain a full erection.

Penile arterial reconstruction A kind of reconstruction surgery to restore the penile arterial supply to meet the sinusoidal demands. The surgery purpose is to restore blood supply, therefore no destruction is allowed.

Penile veno-occlusive Dysfunction Penile sinusoidal tissues sustain blood perfusion from 2 to 3 to 60–80 mL/min to flaccid and erection status respectively. It is, therefore, understandable that abundant blood drains back to systemic circulation. Inability either to attain or maintain a rigid erection occurs if a penile veno-occlusive dysfunction occurs.

Penile vascular surgery Surgery method involves penile vascular system including penile arterial or venous surgery.

Penile vascular intervention A general term of penile endovascular treatment managed by the physician including methods used by the surgeon, interventional radiologist.

Penile venous embolization A measurement in an attempt to block the penile venous drainage by hindering the vessel from vascular endothelium by implanting coil, band ligation or scleronizing agent injection.

Penile venous ligation A ligation of penile erection related veins.

Penile venous sclerotherapy Any method in an attempt to reduce the penile venous drainage speed by using sclerosing agents.

Penile venous stripping A term to describe a thorough removal of erection related veins while the exits of emissary veins are firmly ligated.

Suction apparatus A device to suck bleeding blood away in order to clearly see the operative field during surgery.

Penile Arterial Surgery for Patient with Erectile Dysfunction

Innovative Penile Vascular Anatomy and Erection Physiology

The human beings have been in its current penile anatomy for some three thousand centuries. In traditional medical literature, it is consistently depicted that a single circular tunica layer and one deep dorsal vein flanked by paired dorsal arteries between Buck's fascia and the tunica albuginea of the corpora cavernosa. We may question how the veno-occlusive mechanism elucidates if no outer tunic layer exists? Thus it is likely that we may still not thoroughly understand its anatomy and erection mechanism and so does the reconstructive surgery derived from this anatomical knowledge.

Recent studies substantiate a model of the tunica albuginea of the corpora cavernosa as a bi-layered structure with a 360° complete inner circular layer and a 300° incomplete outer longitudinal coat spanning from the bulbospongiosus and ischiocavernosus proximally and extending continuously into the distal ligament within the glans penis. The entire outer layer of the penis and the above two muscles could be collectively categorized as skeletal components. The inner layer contains and supports the intracavernous sinusoids, the erection-related veins, and artery which could collectively be allocated as the smooth muscle components. Human beings are peculiar within the erect animal family in that we possess an os analog associated with some proportionally large and extraordinarily extensible corpora cavernosa and however, man does not possess an os penis which is present in all quadriceps; the actual bony portion that provides penile rigidity. The erectile capability of the human penis largely depends on sinusoids in the glans penis, the corpus spongiosum, and the corpora cavernosa which are also exclusively responsible for erection rigidity.

Thus, human penis evolves from a rigid body into a hydraulic system. Albeit human may be proud of this penile hydraulic design at no expense of awkward locomotion for an erect animal. It seems that the human corpora cavernosa are vulnerable to encounter erectile dysfunction (ED) which is defined as inability either to attain or maintain a rigid erection for satisfactory coitus.

The importance of a functional penile artery is the prerequisite for rigid erection. A rigid erection of the corpora cavernosa is initiated by either local stimulation or central drive if there are healthy corpora cavernosa in which a unique dual circulatory route is characteristic. In addition to the regular vascular system for nutrition via the capillaries, there is a system for erectile function in

which sinusoids shunt directly from arterial to sinusoidal space and then venous channels bypassing the capillaries. In human corpora cavernosa, therefore, it accounts for 2–3 mL/min to 60–80 mL/min in accordance with flaccid and erection status respectively. The main source of blood supply to the penile sinusoids originates from the internal pudendal artery which is the end branch of the internal iliac artery, although accessory contributions may arise from the external iliac, obturator, vesical, and femoral arteries. The internal pudendal artery gives off branches of bulbourethral, cavernosal and dorsal artery along exiting from the pudendal canal. The sinusoids of the corpora cavernosa are primarily supplied by the cavernosal artery and secondary by the dorsal artery (Fig. 1).

Fig. 1 Schematic illustration showing vascular system in the human penis. (A) Upper Lateral view: The deep dorsal vein consistently in the median position, receives the blood of the emissary veins from the corpora cavernosa and of the circumflex vein from the corpus spongiosum. It is sandwiched by cavernosal veins, although these lie in a deeper position. Bilaterally each dorsal artery is sandwiched by its corresponding medial and lateral para-arterial veins respectively. Note that the lateral para-arterial vein merges with the medial one proximally. The deeper color of the veins indicates the deepest group of the vasculature. The internal pudendal artery gives branch to bulbo-urethral artery and then the cavernosal artery which is the major supplier of the CC as well as dorsal artery supplying the glans penis. (B) Cross-section of the mid-portion: Note that the number of veins is seven rather than that of the traditionally described one, although it becomes four at the level of penile hilum because a merge takes place in each pair of the nomenclature veins. The erection-related veins are arrayed in an imaginary arc on the dorsal aspect of the tunica albuginea. The penile artery does not always accompany fellow veins.

Two types of branches arise from the cavernosal artery. Firstly, the outer capillaries which are responsible for penile nutrition supply the smooth component, skeletal component and nerve fibers. This system signifies that the corpora cavernosa are also susceptible to long hours in the erectile state. Secondly, and for fulfilling erection function, the inner helicine arteries open directly into cavernous spaces without entering capillaries, which are then emptied into the post cavernous venules. These inner arteries are shaped like corkscrews and allow the penis to elongate and enlarge without compromising flow.

The sinusoidal blood drains directly to sub-tunica venous plexus, subsequently passing through the tunica albuginea to the emissary veins, and then to the deep dorsal veins (DDV), cavernosal veins (CVs) and para-arterial veins (PAVs) separately. DDV, CVs and PAVs are collectively called erection related veins (ERVs) because they drain the sinusoidal blood independently. Thus DDV, CVs and PAVs own their specific emissary veins. This new understanding of penile venous anatomy is highly significant. Not only do we consider the traditional deep dorsal vein significant, but also the cavernosal vein, which distributes through the entire penile length and the para-arterial veins. The deep dorsal vein that lies consistently in the median position receives blood from the circumflex veins of the corpus spongiosum and from the emissary veins of the corpora cavernosa. Emissary veins run between the inner and outer layers of the tunica for a short distance, often piercing the outer layer bundles in an oblique manner. Therefore, and significantly, these emissary veins can be easily occluded by the shearing action elicited by the inner circular and outer longitudinal layers of the tunica albuginea.

The DDV is sandwiched by cavernosal veins that are coalesced to one at the penile base. Bilaterally each dorsal artery is sandwiched by the medial and lateral para-arterial vein respectively. Veins from the glans penis form a retrocoronal plexus that drains predominantly into the deep dorsal vein, the urethral veins, and the corpus spongiosum. The deep dorsal vein courses proximally in the midline between the two corpora cavernosa and empties into the periprostatic plexus. The superficial dorsal vein drains the skin and the subcutaneous tissue superficial to Buck's fascia and may have direct shunts to the corpora cavernosa. This, in turn, drains into the superficial external pudendal vein and is frequently seen in young male with ED. If and only if the erectile function of corpora cavernosa is healthy, the penis not only expands in its girth but also increases in its length, resulting in sufficient rigidity with sexual arousal.

Multiple layers of smooth muscle surround the helicine branches. This muscle is contracted while flaccid, allowing only small amounts of blood into the lacunar spaces. After the appropriate stimulus, muscle relaxation occurs and the arteries dilate and straighten, increasing blood flow and dilating the lacunar spaces, in turn, applying pressure against the outer longitudinal layer of the tunica albuginea to reduce the blood drainage, which eventually results in a rigid erection. Application of real world physics would assume that the corpora cavernosa is an ideal vessel to apply Pascal's Law which states that pressure applied to any part of an enclosed fluid at rest is transmitted undiminished to all walls of the containing vessel.

Pathophysiology of Erectile Dysfunction

There is a current consensus of erectile dysfunction pathophysiology which includes psychological disturbance, hormonal imbalance, vascular insufficiency, neurological deficit, sinusoidal fibrosis, pharmacological adverse's effect and metabolism disease. In other words, healthy male with normal sexual function must be under psychological health, an intact neurological system, a normal hormonal profile, an absence of adverse drug influence, a lack of systemic diseases, a functional artery and healthy intracavernous tissues. However, the end-organ penis just requires arterial sufficiency, normal sinusoidal tissue, and functional veins. Although there is no agreement on what would be the major contributor, there is a bias towards endothelial function due to the dramatic effects demonstrated by phosphodiesterase-5-inhibitors (PDE5 ↓) on erectile dysfunction.

There are, however, recent hemodynamic studies on fresh and defrosted human cadavers whereby rigid erections were unexceptionally reproducible despite the lack of endothelial activity. Constant low-pressure perfusion was used to mimic arterial inflow, and the staged removal of ERVs produced increasingly more rigid erections. Could it be that ERVs may, in fact, be the predominant factor that underlies erectile rigidity? Certainly, and in the light of our increased understanding of the penile vasculature, it would at least warrant re-evaluation of the role and even a viable option of venous surgery for erectile dysfunction in addition to rudimentary penile artery reconstruction. In summary, the corpora cavernosa, skeletal muscle components unite smooth muscle components to meet the requirements for an erection and only allow vascular and nervous tissue to communicate with the systemic circulation. Their anatomical relation is seemingly like a cluster of the grape when the emissary vein is regarded as the grape trunk and each sinusoid as a fruit. The rigid erection of the corpora cavernosa overall depends on cooperation among healthy sinusoids, a normal tunica, functional arteries, and competent veins. Thereafter vascular dysfunction is an important cause of male erectile dysfunction. It can be classified as veno-occlusive dysfunction, arterial insufficiency, or mixed. Accordingly, the best resort may be penile venous surgery, arterial reconstruction, and venous/arterial reconstruction respectively.

Penile Artery Surgery

In general, arterial vasculogenic causes of ED increase with age and is most prevalent in those with risk factors for atherosclerosis such as diabetes, hypertension, cigarette smoking, hyperlipidemia and obesity. Traumatic events, which occur more often in younger men, are due to pelvic trauma, straddle injury or even perineal insult such as long time bicycling. Albeit it is not above

controversy, documentation of arterial insufficiency can be noted via color Doppler ultrasonography, if peak systolic velocity is <25 cm/s or simple prostaglandin E1 test if the response fails to reach rigid erection.

Angiography, the benchmark for all arterial investigations, is reserved for those males who may resort their ED to penile arterial reconstructive surgery, concurrent embolization or angioplasty for treatment of arterio-venous fistula or stenosis respectively.

In 1973, Michal published firstly an article of penile arterial reconstruction in an attempt to enhance arterial flow to corpora cavernosa. He debuts revascularization surgery by the anastomosis of the inferior epigastric artery (IEA) to the corpora cavernosa. Subsequently, the deep dorsal vein arterializations, either without extensive ligation of the circumflex veins or with venous ligation, were introduced by Virag and Haudi in 1981 and 1986 respectively. In an effort to achieve more favorable outcomes varied modifications were performed, such as Furlow–Fisher procedure in which IEA was made in an end-to-side anastomosis to the DDV while several ligations were undertaken at the lateral circumflex veins, proximal and distal location (Fig. 2). It aims at increasing penile arterial inflow and limiting the venous drainage. Postoperative outcomes of arterial revascularization surgery are varied due to multifaceted causes, patient selection, surgical instruments and surgical technique. In general, its merit is limited, without long term benefits (Table 1). Furthermore, complication rate occurs in about 25% of patients who undergo penile revascularization surgery. Immediate postoperative arterial hemorrhage may result from disruption of the microvascular anastomosis with hematoma formation. The potential risks of these techniques, such as spongy necrosis and hyperesthesia of the glans, cannot be ignored. In addition, a complication rate of wound infection, inguinal hernias, loss of penile length, and decreased penile sensitivity cannot be avoided. Particularly, the major complications are priapism and glans hyperemia which deter continuing existence. Not surprisingly, it has been regarded as experimental among most urological surgeons. Although it is not beyond controversy, penile arterial revascularization surgery has been studied by several teams and supports its utility in young males suffered from arterial trauma, and in the older male with localized arterial occlusive disease (Fig. 2A). Endovascular angioplasty with stenting is also recommended as a minimally invasive option for this disease entity.

Fig. 2 Selective internal iliac arteriography. (A) An aortogram disclosed marked stenosis (arrows) of internal iliac artery bilaterally. It should not be prognostic for arterial revascularization. (B) A similar phase arteriogram showed a blockage of penile dorsal and cavernosal artery, whereas the spongiosal artery appeared diffusely profuse to the corpus spongiosum after a straddle injury in a 32-year-old man. Is it similar to an arterio-venous malformation? The Foley catheter (arrow) was clamped. The pudendal artery was well demonstrated (arrows), therefore, was this male a good candidate for arterial reconstruction? (C) Illustration of Furlow–Fisher procedure. The inferior epigastric artery is fashioned to the deep dorsal vein which is ligated distally, proximally and lateral locations of the circumflex veins. (D) Photo of an already DDV (yellow traction) arterializations with IEA. The microvascular anastomosis was performed.

^bF–F is an abbreviation of Furlow–Fisher procedure.

^cN/A stands for non-applicable.

Penile Venous Surgery for Patient with Erectile Dysfunction

Conventional Penile Venous Ligation Surgery

In 1873, the Italian Francesco Parona injected varicosity dorsal penile vein of an impotent young patient with hypertonic saline in order to cause sclerosis and reduce the excessive venous outflow by this. Subsequently, surgical dorsal vein ligation or resection was practiced by several American doctors, e.g. Henry Raymond and James Duncan each in 1895, Joe Wooten in 1902 and mainly Frank Lydston in 1908, who reported on 100 resections. Beginning in the 1930's Oswald Swinney Lowsley combined simple dorsal vein plication with a surgically more advanced perineal crural technique in which he plicated the bulbocavernosus and ischiocavernosus muscles with several mattress sutures. Penile venous surgery (PVS), however, remained unpopular until 1980's when the majority of patients with organic erectile dysfunction were subject to veno-occlusive dysfunction (VOD), the procedure took place and prevailed accordingly. The approach was expanded from initial procedures involving single vessel ligation of the deep dorsal vein to more elaborate techniques in which excision of the deep dorsal vein, cavernous vein, as well as the crural vein were described. It appears that the offending veins of VOD are merely a single DDV with tributaries, additionally crural veins and cavernous veins which drain the penile hilum.

Importantly, though anatomically the penis is in the realms of urology, the delicate microsurgery is beyond the traditional urology training, which may result in an inadequate skill level leading to just a single ligation at the expense of electrocautery influence. Not surprisingly penile venous ligation has been almost abandoned because the consensus on this type of treatment for erectile dysfunction (ED) is short term success of 1 to 2 years, without a sustainable long-term outcome. In addition to the lack of sustained functional improvement, irreversible deformity and permanent numbness of the penis after surgery were frequently noted and considered to be unacceptable complications. Failure to achieve a long-term merit for ED and the seemingly, unavoidable, adverse side effects have discouraged many surgeons from applying venous surgery for patients with ED. However, irreversible numbness results from nerve damage, and penile deformity is a result of either fibro-skeleton alteration or loss of extensibility and sliding capability of layered tissues from electrocoagulation-induced fibrosis. Should then neither nervous nor fibrous tissues not be innocent if PVS is exclusively targeting on venous structures? Should the venous removal be sufficient if all conventional penile venous anatomy has exclusively depicted a single DDV and tribute veins nearby the penile hilum?

Consensus of Penile Vascular Surgery

Penile arterial revascularization is considered to be unproven and controversial. In 1996, it was the first consensus reached when the AUA (American Urological Association) in its guidelines considered penile venous and arterial surgery in men with arteriosclerotic disease as investigational and should be performed only in a research setting with long-term follow-up available. The proceedings of the First Paris International Consultation on Erectile Dysfunction in 1999, the second in 2003 and the third in 2009 were in tandem with the AUA guidelines. Similarly, in 2005, the AUA Update on the Management of ED, and the ISSM's Standard Practice in Sexual Medicine textbook maintained the consensus. However, it may deserve reappraisal after a review of arterial reconstructions reported after 2004 (Table 1), including Kawanishi and Vardi in 2004, Kayigil in 2008, Munarritz in 2009 and Kayigil in 2012. Interestingly, researchers unexceptionally report positive long term outcomes when both penile arterial and venous reconstruction are incorporated, suggesting arterial reconstruction alone is not sufficient to long term restoration of ED.

For investigating the vascular contribution exclusively, hemodynamic studies have been performed on both fresh and defrosted human male cadavers since 2001 to 2013. In each case, a rigid erection was unexceptionally attainable under very low infusion rate following venous removal. This clearly has significant ramifications in relation to vascular reconstruction and its role in treating ED patients. Albeit there are no comparative prospective randomized studies assessing outcome of penile revascularization surgery for arteriogenic ED. Based on the evidence in the literature, this surgery may be offered to men below the age of 55 who are

non-smokers, non-diabetic, show no evidence of venous leakage, and demonstrate an isolated stenosis of the internal pudendal artery in particularly to young patients who have sustained focal arterial injury due to trauma. Regarding penile venous surgery for patients with VOD, it is rejected by most medical community due to disappointing outcomes and unavoidable complication such as permanent penile numbness and penile deformity. Although, use of electrocautery is routine in surgery, it is a major avoidable hazardous in penile venous surgery while penile sinusoids are too delicate to sustain a back fire. The second reason for unsuccessful-conventional PVS is incomplete removal of offending veins for VOD if the PVS refers to the conventional penile venous anatomy. Both residual veins and electro-cautery effects are readily demonstrated in those patients whom underwent PVS somewhere internationally since 2001.

Chronological Development of a Refined Penile Venous Stripping

The advancements in our understanding of penile anatomy, in our surgical instruments and our surgical techniques have resulted in our performing on an ambulatory basis PVS on over 3000 men since 1986 (Table 2). After microsurgery drill on rat and human cadaveric dissection of the entire penile structure in 1985, neither a Bovie nor a sucker has been used with our penile venous stripping techniques. In 1986, we introduced penile venous ligation of the proximal DDV in an initial study of 8 males. This simple procedure was replaced by venectomy very soon thereafter and then by venous stripping which was based on the single DDV conventional penile venous anatomy until 1999. The rate of successful intercourse improved from 50% to 91% in the past decade.

During 1999, 35 patients underwent repeat cavernosography because of the gradual decrease in the erectile capability that occurred in a period of 6 months to 7 years postoperatively. Imaging demonstrated some excessive veins - cavernosal and para-arterial veins, which were further confirmed in cadaveric dissections. By then, the revolutionary edition of erection-related veins in the human penis was regarded as a blueprint for venous stripping surgery. The latest method of penile venous reconstructive surgery is based on a circumferential incision plus a median pubic longitudinal approach via a specific key instrument with an acupuncture assisted local anesthesia on an ambulatory basis. Since the penile venous surgery is exclusively directed at the veins, damage to non-venous soft tissues has been avoided. Tissues like nerve, artery, and lymphatic vessels are spared. Since June 1988, we have performed the penile venous stripping procedure as an outpatient surgery under local anesthesia. Neither a Bovie nor a suction apparatus has been required in the entire procedure, resulting in minimal or no injury to any tissue other than the veins. The incision is small and delicate.

The latest refined penile venous stripping

In medical history, it is rare to encounter a surgical procedure like venous surgery for restoring erectile function that has sustained such an extended period of disrepute. For over a century, the merit for conducting penile venous surgery to treat ED has never been firmly established. It was believed to be indicated only for <1% of patients with ED secondary to veno-occlusive dysfunction (VOD). Recent studies, however, show that VOD may be more prevalent in patients with ED, and even in those with ED ascribed to penile arterial insufficiency. Thus, the prevalence of VOD may be greater than expected suggesting that a larger proportion of

Table 2 Chronological refinement in penile venous stripping surgery methods since 1986

Methods	No.	Age (Year)	Time period	Op. time (hours)	IR* (%)	SR* (%)	Follow-up period (years)	Anatomy blueprint

Total	3097	19–91	1986–2015	0.5–8.0	<50–95.7	0–85.3	5–32.0	Unpublished data, ultimate method of USPTO* patent

*The DDV, CV, PAV, IIEF, USPTO, IR & SR are an abbreviation for the deep dorsal vein, cavernosal veins, para-arterial veins, international index of erectile function, The United States Patent and Trademark Office, improvement rate and satisfaction rate respectively.

patients with ED may be suitable for venous surgery. In contrast to the feared potential recurrence of conventional penile venous surgery, <25% of our 3000 patients on whom the operation was performed have complained of a recurrence. The overall outcomes are commensurate with method refinement over several decades.

The most advanced method of penile venous stripping—as depicted on the United States Patent and Trademark Office (USPTO) website—for treating impotence resulting from veno-occlusive dysfunction. A circumferential incision was first made while a circumcision was completed if required (Fig. 3). A more extensive degloving of those tissue layers superficial to the Colles' fascia was then undertaken. A milking manipulation is helpful to enhance the visibility of the DDV which is stripped proximally with a pull through technique via an opening made on the buck's fascia from opening to opening on the Buck's fascia until the penile base using a 6-0 nylon suture. Likewise the paired cavernosal veins (CVs) were stripped. For accessing the deep seated venous vessels a median longitudinal pubic incision skin was used to continue the venous stripping. The paired proximal stumps of the DDV and the CVs served as a guide, and the DDV was then firstly thoroughly stripped and then ligated with a help of 85° hemostat as far as the infra-pubic angle. Similarly, the deep-seated CVs are managed. The paired para-arterial veins (PAVs) which sandwich the dorsal arteries bilaterally were meticulously ligated rather than stripped. Smaller veins between the tunica albuginea and the Buck's fascia were identified by squeezing the sinusoids of the corpora cavernosa. The wound was closed with 5-0 chromic catgut and 6-0 nylon sutures. A compression dressing was placed such that it encircled the penile shaft. Follow-up cavernosograms is routinely undertaken immediately postoperatively or intraoperatively if required (Fig. 4). Postoperative cavernosograms categorically confirmed that the CCs are an ideal chamber for intracorporeal fluid retention in all patients, particularly, the penile crura was unexceptionally stronger radiopaque than that of femoral cortex (Fig. 4D, E & F vs. A & C).

Despite those drawbacks of conventional penile venous surgery, our penile venous stripping has been developed with the inspiration of patients' positive response in tandem with the advances of penile tunical and venous anatomy associated with the erection

Fig. 3 Photos of the ongoing penile venous stripping process. (A) A longitudinal pubic incision was marked (dotted line) and preputial approach was performed to access the offensive veins, DDV (arrow) and CV (dotted arrow), which were managed and clamped with hemostat respectively. Note that tag suture was made at the junction between the corpus spongiosum and corpora cavernosa for fixation of the circumflex veins. The visibility of the deep dorsal vein (DDV) was enhanced by employing a milking manipulation, mimicking a squeeze applied to a balloon, of the corpora cavernosa. (B) The circumflex vein was managed while each emissary vein was ligated with 6-0 nylon closest to the outer tunical layer. Eventually, the venous channel was free from blood. (C) The venous plexus of DDV (arrow) and CV (dotted arrow) was stripped by 4–5 pull-through maneuvers until the pubic level encountered. (D) The venous plexus was passed underneath via a public longitudinal approach to relay the penile venous stripping. (E) The venous stump was relayed smoothly. Note the DDV (arrow in D) and CV (dotted arrow in D) were managed in an entire group in this case. (F) The first branch of the DDV was managed. (G) 7–9 big branches of DDV were managed one by one until the infra-pubic angle was met. (H) The DDV (arrow) was managed completely, then the CV was likewise managed while 5–8 branches were firmly ligated with 6-0 nylon. (I) Finally, the preputial (dotted arrow) and longitudinal pubic (arrow) wounds were fashioned with 5-0 chromic sutures respectively. Note that neither an electrocautery nor a suction apparatus was required in the entire procedures.

Fig. 4 Dural pharmaco-cavernosography of veno-occlusive dysfunction and cavernosographic evidence of erection restoration. (A) The first cavernosogram was obtained while a 10-mL diluted iohexol solution was intracavernously injected, resulting in the immediate opacification of the DDV (*asterisk*), CV (*cross*) and then preprostatic plexus. Note the volcano-like eruption of emissary veins. (B) A cavernosogram was obtained after further injection of the 10-mL solution, while the drainage veins were remarkable at the penile hilum. (C) A pharmacocavernosograms was obtained 20–30 min after 20 μ g of prostaglandin E1 (test) was intracavernously injected. The bulking of drainage veins were relatively prominent despite a rigid erection attained. Thus a veno-occlusive dysfunction was documented. (D) An intraoperative cavernosogram disclosed most offensive veins was stripped but an accessory cavernosal veins and several circumflex veins were left. (E) An immediate postoperative cavernosogram showed the penile venous stripping was complete. (F) Further intracavernous injection confirms an ideal milieu to apply intracavernosal fluid retention. Note D, E and F were postoperative ones in which the penile crura was unexceptionally stronger radiopaque than that of femoral cortex.

mechanism since 1986. We applied chronologically refined stripping techniques in a large patient population under acupuncture-assisted local anesthesia on an ambulatory basis. We consistently encounter patients seeking this treatment because of poor functional outcomes and unexpected adverse effects of prior penile vascular interventions internationally. Although currently we recommend this treatment only to patients who are nonresponders to phosphodiesterase-5 (PDE-5) inhibitors, we always fail to decline this sort of patient. Penile venous surgery has likely been innocently condemned; the abandonment would be more appropriate if its justification shifted from the surgery itself to the method of surgical manipulation. We heretofore suggest its ban should be lifted to help males that suffer from ED. Surely its efficacy and safety warrant well-structured, randomized, and controlled research by surgeons who know the anatomy well and are well-equipped with microvascular surgery skill without the necessity of electrocautery.

Varied Endovascular Intervention for Patient with Erectile Dysfunction

Penile endovascular interventions, both angioplasty and venous embolization, aim to treat VOD or arterial insufficiency via limiting the outflow of blood or increasing arterial inflow in the penis, respectively. It may be technically easy for physicians to implant, owing to simplicity and reproducibility, and it is a minor procedure for patient because of low morbidity. Consequently, pudendal stents and penile venous embolization with or without sclerotherapy have been repeatedly introduced for treating VOD and arterial insufficiency correspondingly. It is effective and safe in some vascular diseases. On the elusive ED issue, what great news to patients if endovascular treatment of vasculogenic erectile dysfunction works. Among options for venous treatment, penile venous embolization is an old paradigm newly revisited by the intervention radiologist. It is commonly believed to be minimally invasive and safe.

Refractory ED has prompted five international males to seeking our penile venous stripping since late 2012 despite coil venous embolization with sclerotherapy was performed elsewhere. Stunningly, uncontrolled coils not only lodged in pulmonary artery, but also made a right cardiac ventricle perforation (Fig. 5A) which is confirmed by a contrast computerized tomography. An acute chest pain occurred in a 25-year-old male resulting from the uncontrolled coils traveling to right pulmonary artery just in seven days after

Fig. 5 Imaging of patients received prior coil embolization and sclerotherapy elsewhere internationally. (A) Coils migrated to lodge in left and right pulmonary artery respectively, and one coil perforated the right cardiac ventricle (*purple arrow*) which is further confirmed by a contrast computerized tomography. (B) The inserted coils (*purple arrow*) migrated to right lower pulmonary artery, which caused an acute chest pain. (C) An insufficient rigidity of erectile penis suffered a 25-year-old patient albeit dozens of coils (*purple arrow*) were inserted in an attempt to limit the penile venous drainage. Note the venous buckle (*green asterisk*) was remarked. (D) The preprostatic veins (*green asterisk*) were blocked and engorged despite many coils were inserted (*purple arrow*).

coils inserted (**Fig. 5B**). On limiting the VOD drainage, an insufficiently erectile rigidity resulting from blockage of the deep dorsal vein and cavernosal veins distal to the preprostatic plexus (**Fig. 5C**) and a consistently unacceptable erection quality resulting from failing venous blockage was noted (**Fig. 5D**). Therefore, the efficacy of endovascular therapy is not beyond controversy, and its safety may not be sustainable. This implies that a penile venous embolization coil is at risk of migrating throughout the body once it is inserted in the main common drainage channel of corpora cavernosa.

Accordingly, the efficacy of venous embolization warrants research because it just treats vascular channels outside the corpora cavernosa. Pulmonary migration of coils inserted for treatment of erectile dysfunction caused by venous leakage was reported in 1993. This can lead to symptoms such as acute chest pain and chronic cough. An uncontrolled coil is capable of traveling more than just the pulmonary arteries, and may also perforate the ventricular wall. The tension of embolization coils varies by manufacturer, as does the coils' penetration ability. So potentially severe morbidity of coils, though rare, should be borne in mind, and patients should be informed of this possibility in choosing coil embolization for treating ED resulting from veno-occlusive dysfunction.

The past 3 decades have seen an explosion of new technologies, devices, gadgets and application of state-of-the-art tools to medicine and surgery professionals. Penile vascular reconstructive surgery and endovascular intervention are significantly beneficial from this trend. It ought to be promising in the near future if and only if the sound method is used via valid instruments and appropriate technology.

Summary

New insights into penile tunical and venous anatomy, and erection physiology have been made in recent decades. They have underpinned penile morphological reconstructive, penile endovascular intervention as well as penile vascular surgery. Although vascular reconstructive surgery is still regarded as experimental, anatomical-based techniques of vascular reconstruction should be reappraised. Arterial reconstruction has been shown to be beneficial to young healthy males who sustain trauma. Older healthy ED males are more likely to benefit if the vascular surgery includes both arterial revascularization and veno-arterIALIZATION. The reproducible refined penile venous stripping procedure which has been developed and refined over several decades is showing promise as a viable solution for veno-occlusive dysfunction across all ages.

Surgical Correction for Peyronie's Disease and Anatomic Abnormalities of the Penis

M Ryan Farrell, Peter Tsambarlis, and Laurence A Levine, Rush University Medical Center, Chicago, IL, United States

Introduction

Background

Initial descriptions of a disorder of penile curvature were first noted in the 13th century by Borgognoni and Saliceto followed in 1561 by Fallopius and Vesalius. Later, in 1743, Francois de la Peyronie further described and treated a condition involving rosary beads of scar tissue along the dorsal aspect of the penis with associated dorsal curvature during erections that now carries his name—Peyronie's disease (PD) (De la Peyronie, 1743).

PD is regarded as an acquired wound healing disorder of the tunica albuginea of the corpora cavernosa that results in the formation of a fibrotic, inelastic scar (Smith, 1966). The scar tissue causes penile deformity that commonly includes curvature, shortening, indentation, hinge effect, painful erections and erectile dysfunction (ED). The perceived narrowing and loss of length can have a substantial psychological impact leading to depressive symptoms and negatively impacting relationships (Rosen et al., 2008; Smith et al., 2008).

Epidemiology

The incidence of PD has been reported in 3%–9% of men (Schwarzer et al., 2001; Mulhall et al., 2004). However, given the psychosocial implications of this condition and the resulting reluctance of patients to report penile deformity and seek treatment, the actual incidence of PD may, in fact, be higher.

Men in their 5th decade of life have the highest prevalence of PD. Further, the incidence of PD increases with age as demonstrated by a large European survey by Schwarzer et al. (2001). Over 4000 men responded and 1.5% of men age 30–39 years reported an area of penile induration, which increased to 6.5% in men over 70 years old. It is speculated that the increased incidence of PD with age is the result of contributions from comorbid conditions that also have increased prevalence with age and include diabetes, hypertension, and hyperlipidemia.

Etiology and Pathophysiology

The etiology of PD has not been completely elucidated. PD is thought to be initiated by penile trauma or microtrauma that causes subtunical bleeding. In genetically susceptible individuals, this results in a localized inflammatory response that includes tumor growth factor beta. The subsequent cascade of cytokines and free radicals, cell cycle dysregulation, genotypic changes, and biological transformation of the tunica albuginea leads to fibronectin and collagen deposition in the extracellular matrix and ultimately scar formation. The resulting inelastic segment of the tunica albuginea leads to the characteristic penile deformity of PD (El-Sakka et al., 1997; Mulhall et al., 2002; Nachtsheim and Rearden, 1996; Schiavino et al., 1997; Cantini et al., 2008; Ryu et al., 2009). While 13% of patients may experience some spontaneous regression of PD, the lack of normal scar remodeling results in 47% of men experiencing no change in deformity over time, and 40% experiencing disease progression (Gelbard et al., 1990). One important characteristic of this wound healing disorder is that the scar does not resolve due to absent remodeling. This has been shown to be associated with inactive metalloproteinases with elevated tissue inhibitors of matrix metalloproteinase (TIMP) (Del Carlo et al., 2008).

Most men with PD receive conservative therapy as initial treatment. Various modalities exist including oral medication, topical agents, intralesional injections, electromotive drug administration, extracorporeal shock wave therapy, and penile traction (Gholami et al., 2003; Larsen and Levine, 2012). However, when the disease is in the stable phase, surgery remains the gold standard modality, as it offers the most reliable and definitive treatment for PD.

Other Abnormalities of the Penis

Chordee represents a pathology, which is unique from PD. For the sake of this discussion “chordee” will be the term used to describe congenital curvature of the penis, chordee without hypospadias, and monosymptomatic curvature. As such, this discussion is also referring to curvature of the penis with the urethral meatus in an orthotopic location. Critical to this discussion is the ability to differentiate chordee from PD. At a simplistic level, chordee is congenital and, by definition, PD is acquired. The etiology of chordee is believed to be a dysplasia of the penile corporal tunica albuginea which reduces elasticity around the dysplastic area. When the affected male obtains an erection the dysplastic portion of the tunica albuginea does not expand to the same degree as the surrounding normal tissue. This results in a curve towards the dysplastic area (Nyirády et al., 2008). This is distinct from the fibrotic scarring process described above.

The classic presentation is during puberty when the affected male becomes more aware of the aesthetic appearance of his erection. A subset of these men have a curve which is severe enough to impair or prevent successful penetrative intercourse. These are the men who warrant evaluation for potential surgical intervention. Nesbit was the first to describe surgical correction of chordee, which involved excision of ellipses of tunic on the convex side of the curvature followed by transverse suturing (Nesbit, 1965). The Heineke-Mikulicz technique was a modification where longitudinal incisions are made in the corpora on the convex side followed by transverse suturing (Yachia, 1990). The authors, however, advocate for a tunica albuginea plication (TAP), which will be described in greater detail in the following sections. Other congenital pediatric abnormalities of the penis such as extrophy, penile duplication, and micropenis are beyond the scope of this article.

Preoperative Evaluation

A thorough preoperative evaluation is necessary for surgical planning and includes a patient history, physical exam, and diagnostic imaging. A detailed history should include questions regarding time of onset, preceding trauma, pain, curvature, shortening, hinge effect, indentation, and erectile function. Between 8% and 40% of men with PD, 20% in our experience, recall a traumatic event that preceded the onset of curvature (Tal et al., 2012; Jarow and Lowe, 1997; Chung et al., 2012). Patients should be asked to subjectively describe their erection quality on a scale of 0–10, with 7 being defined as an erection that is adequate for penetration with manual assistance. Erect penile curvature should be assessed from the patient perspective to evaluate individual preoperative perceptions. It has been shown that only 20% of patients accurately describe their curvature, with 56% overestimating and 26% underestimating curvature by a mean of 20 degrees from the objective measurement (Bacal et al., 2009). Further, patient described penile shortening should be investigated. Shortening is reported in 70% of patients and can range from 1 to 10 cm in length lost, making this particularly distressing for patients (Rosen et al., 2008; Smith et al., 2008).

An understanding of erectile function prior to and following the development of PD is critical for operative planning. ED may be related to the pathophysiology of PD itself, the psychological effect of PD, or the result of pre-existing comorbidities including diabetes, peripheral vascular disease, and smoking (Rosen et al., 2008; Levine and Coogan, 1996).

The physical exam is directed at the penis. The plaque should be palpated and its location noted. Stretched flaccid penile length is measured over the dorsal aspect of the penis from the pubis to the corona (Wessells et al., 1996). An evaluation of stretched penile length can be useful to track progression of disease or for comparison after treatment.

Diagnostic imaging with dynamic duplex ultrasound with vasoactive injection of papaverine, prostaglandin E1, or trimix is essential in order to determine appropriate management. At this point, several characteristics can be objectively assessed including erect deformity, curvature, plaque calcification, indentation, hinge effect, and erectile response (Ralph et al., 2010).

Indications for operative intervention for men with PD are based on expert opinion and include: stable disease—at least 1 year from onset and at least 6 months with stable deformity, inability to engage in penetrative intercourse due to deformity and/or inadequate rigidity, failure of non-surgical management, extensive plaque calcification, and patient desire for the most rapid and definitive corrective modality following disease stabilization. Penile pain is a relative contraindication to surgery, with the exception of pain resulting from curvature-associated torque on the erect penis (Ralph et al., 2010).

There is a well established algorithm for the operative management of PD (Levine and Larsen, 2013; Levine and Lenting, 1997). For men with adequate rigidity for penetrative intercourse with or without pharmacotherapy, tunica albuginea plication (TAP) versus plaque incision or excision and grafting (PEG) can be considered. TAP is most appropriate for patients with curvature < 60–70 degrees, no hourglass or hinge effect, and anticipated loss of erect length < 20%. In contrast, PEG can be utilized for individuals with curvature > 60–70 degrees, extensive plaque calcification, and/or presence of hinge effect resulting in an unstable erection. Importantly, candidates for PEG must have strong preoperative erections, as there is an increased risk of postoperative ED that should be discussed with the patient prior to proceeding with the operation.

Men with ED who do not respond to pharmacotherapy should be considered for placement of a penile prosthesis in an effort to improve rigidity and curvature. Should there be residual curvature after placement of the prosthesis, manual modeling can be attempted (Wilson and Delk, 1994). If a curve of > 30 degrees remains, an incision of the tunica albuginea can be performed over the point of maximum curvature. If the incision results in a defect > 2 cm, a biograft should be placed, which prevents herniation of the prosthesis and prevents cicatrix contracture (Levine and Dimitriou, 2000).

Preoperative counseling is necessary to establish patient expectations for a successful surgery. The possibility of persistent curvature, decreased rigidity, loss of penile length and diminished sensation should be discussed. A successful straightening procedure involves establishing a functionally straight penis, which is defined as a residual deformity of 20 degrees or less (Ralph et al., 2010). Decreased rigidity occurs in up to 50% of men and may require treatment with PDE5 inhibitors, injection therapy, vacuum devices, or subsequent placement of a penile prosthesis. The occurrence of decreased postoperative rigidity depends on preoperative erection quality. Overall, > 5% of patients experience diminished postoperative rigidity, while among patients with suboptimal preoperative rigidity, the incidence increases to > 30% (Taylor and Levine, 2007). Because penile shortening is already a particularly troublesome occurrence for patients with PD, a discussion involving the possibility of further loss of length from corrective surgery is important. Loss of length is more likely with TAP than with PEG. Approximately 20% of men report decreased penile sensation following surgery. Hyperesthesia or diminished sensation in the acute postoperative period generally resolves in 6–12 months (Taylor and Levine, 2008; Ralph et al., 2010).

Surgical Management of Peyronie's Disease

Shortening Procedures

Technique

The principle of TAP is to shorten the longer or convex side of the tunica albuginea in order to achieve the length of the shorter or concave side. After general anesthesia is administered, the lower abdomen, genitalia and perineum is shaved, prepped, and draped creating a sterile field. IV antibiotics are administered in accordance with American Urological Association guidelines and generally involve use of a 1st generation cephalosporin or alternatively clindamycin (Wolf et al., 2012). The stretched flaccid penile length is measured from the pubis to the corona and an artificial erection is induced with injection of saline or a vasoactive agent into the corpora cavernosa. The erect penis is then evaluated noting degree of curvature, location of point of maximum curvature, as well as narrowing, and hinge effect if present. A circumferential, circumcising incision is made 1.5–2.0 cm proximal to the corona and the penis is degloved allowing for exposure of Buck's fascia along the entire length of the shaft. Buck's fascia is then elevated from the tunica albuginea in the area of anticipated plication on the convex side.

At this point, a number of plication techniques are available to the surgeon. The Nesbit procedure involves excision of a transverse elliptical wedge of tunica albuginea on the contralateral side of the point of maximum curvature. The defect is closed transversely with permanent suture (Andrews et al., 1999). Alternatively, the Yachia procedure can be utilized, which incorporates the Heineke–Mikulicz technique (Yachia, 1990, 1993). A full thickness, vertical, 0.5–1.5 cm incision is made through the tunica albuginea contralateral to the point of maximum curvature and closed transversely. The 16 dot procedure involves plication with Lembert-type permanent suture without incising the tunica albuginea (Brant et al., 2007). Finally, the Duckett–Baskin technique as modified by Levine may be utilized (Baskin and Duckett, 1994; Levine, 2006). This involves making two parallel transverse incisions opposite the point of maximum curvature 1.0–1.5 cm in length and 0.5–1.0 cm apart, depending on the desired degree of shortening. The incisions are made through the outer longitudinal fibers of the tunica albuginea leaving the inner circular fibers intact and the tissue between incisions is thinned. The goal is to reduce the redundant tunic between the incisions that occurs after plication, while reducing the likelihood of postoperative ED. Plication is performed transversely using a single permanent suture in an inverted mattress fashion and Lembert stitches with absorbable suture can be used to further reinforce the plication. The authors advocate for use of a limited number of permanent sutures, as we have found that there are fewer palpable nodules with no increased risk of recurrent curvature.

Once plication has been completed and hemostasis has been achieved, an artificial erection can be induced to ensure the deformity is adequately corrected. Buck's fascia is then closed. The dartos fascia and superficial tissues are closed along the subcoronal incision. We utilize ropivacaine to perform a penile block. Xeroform gauze is placed over the incision and a Coban (3M, Maplewood, MN) wrap is placed from distal to proximal over the penile shaft for light compression. Fluff dressing is placed over the penis and scrotum and covered with light compression underwear. The patient is often discharged on the same day as surgery. Dressings are removed on postoperative day 3.

Outcomes

Successful straightening following TAP can be expected in 29%–93% of patients, with patient satisfaction in 65%–96%. Success appears to be similar across the various plication techniques, however, shortening is not corrected. Loss of length has been reported in 18%–100% of patients following TAP and is more likely in men with ventral curvature that is > 60 degrees (Greenfield et al., 2006). Additionally, hinge effect is not addressed. Instead, performing TAP in patients with hinge effect may result in an unstable penis.

Complications with TAP include ED in 3%–38%, recurrent curvature of > 30 degrees in 8%–20%, penile narrowing or induration in 0%–17%, suture granuloma or bothersome knots in 0%–34%, diminished penile or glans sensation in 0%–48%, hematoma 0%–9%, phimosis in 0%–5%, and urethral injury in 0%–1% (Levine and Larsen, 2013; Tornehl and Carson, 2004).

Lengthening Procedures

Technique

PEG is indicated for men with strong preoperative erections and greater disease complexity including greater degree of curvature (> 60–70 degrees), presence of hinge effect, significant narrowing, or extensive plaque calcification. The procedure is initiated after administration of general anesthesia, along with shaving, preparing, and sterile draping of the lower abdomen, genitalia, and perineum. IV antibiotics are administered as above with the TAP procedure according to American Urological Association guidelines (Wolf et al., 2012). The stretched flaccid penile length is measured and the erect penis is evaluated following intracavernosal injection of a vasodilating agent (PGE1 or combination alprostadil, papaverine, and phentolamine). A circumcising incision is made and the penis is degloved.

In cases of dorsal curvature, Buck's fascia is elevated off the dorsolateral aspect of the penile shaft to expose the point of maximum curvature. The neurovascular bundle is then elevated off the dorsal aspect of the penile shaft. With the penis fully erect, the point of maximum curvature is again identified and the area of tunica albuginea is excised leaving a square or rectangular defect. The length of the lateral longitudinal defect should be equal on both sides to correct curvature. The corners of the excised tunic are darted radially to prevent cicatrix contracture and stay sutures are placed in each of the corners as well as at the midpoint transversely both proximally and distally. After appropriate sizing, the selected graft material is sutured to the tunica albuginea first via the stay

sutures and then in a running fashion. An artificial erection is again established and significant residual curvature (<30 degrees) may be further corrected via TAP.

Given the concern for erectile dysfunction resulting from excision of large plaques, plaque incision and grafting (PIG) can be utilized as an alternative to PEG. Once Buck's fascia and the dorsal neurovascular bundle are elevated, a relaxing H shaped incision is made to expand the tunica albuginea and a graft is placed (Gelbard, 1995; Lue and El Sakka, 1998). This may be best used when there is no significant hourglass indentation.

Following PEG or PIG, Buck's fascia is closed with running suture on each of the ventrolateral aspects of the penis and the skin is closed. Our approach to penile block and dressing is as described above for the TAP operation.

Graft material

Multiple graft materials have been utilized including vein (Montorsi et al., 2000), synthetic material (Licht and Lewis, 1997), tunica vaginalis (Das, 1980), dura mater (Sampaio et al., 2002), porcine small intestine submucosa (SIS) (Knoll, 2001), and cadaveric human or bovine pericardium (Usta et al., 2003; Egydio et al., 2002; Chun et al., 2001). The optimal graft has properties similar to that of native tunica albuginea including comparable strength, elasticity, thickness, and pliability. Further, it should be inexpensive, easy to manipulate, carry a low risk of transmitting infection, and should elicit minimal tissue reaction (Gur et al., 2011; Kadioglu et al., 2007). Allograft use requires graft harvesting from a second surgical site with associated comorbidities and complications and is used less commonly as a result. Synthetic materials including polytetrafluoroethylene (PTFE, Teflon) and polyethylene terephthalate (PTFE, Dacron) have fallen out of favor due to the risk of transmitting infection, postoperative inflammation, and resulting fibrosis (Devine et al., 1997; Brannigan et al., 1998).

Currently, the most common grafts in use are the processed cadaveric human pericardium (Tutoplast, Coloplast US, Minneapolis, MN) and the porcine SIS (Surgisis ES, Cook Urological, Spencer, IN) (Hellstrom, 1994; Hellstrom and Reddy, 2000; Knoll, 2001; Levine and Estrada, 2003). We prefer human cadaveric pericardium because it holds suture well and is strong, thin, and there are no reports of rejection or infection in over 2 million cases where this graft has been used. The tissue is processed into an acellular matrix, which elicits native tissue growth with minimal inflammatory response (Tornehl and Carson, 2004). Chun et al. reported that 92% of patients were able to achieve an erection rigid enough for successful coitus with or without assistance (Chun et al., 2001). SIS grafts are also processed into an acellular matrix with similar properties to cadaveric pericardium. However, graft contraction can occur leading to recurrent curvature in 37%–57% of cases (Santucci and Barber, 2005; John et al., 2006; Breyer et al., 2007; Kovac and Brock, 2007; Taylor and Levine, 2008). When sizing the graft to the measured defect in the tunica albuginea, cadaveric pericardium should be no more than 10% larger, while the SIS graft should be at least 25% larger.

There are multiple tissue engineered graft materials under investigation including autologous tissue engineered, adipose tissue-derived stem cell seeded SIS, and human acellular matrix grafts (Ma et al., 2012; da Silva et al., 2011; Schultheiss et al., 2004). Tissue engineered grafts may represent the future of lengthening procedures for PD, however, further investigation is required before these grafts can be utilized in clinical practice.

Outcomes

ED is a common complication of lengthening procedures. Often, men with excellent preoperative rigidity are able to maintain spontaneous erectile function postoperatively. However, men with moderate preoperative rigidity may develop ED postoperatively and require pharmacotherapy—men with poor preoperative erections will continue to have poor erections postoperatively. Postoperative ED has been reported at 0%–30% overall (Taylor and Levine, 2008; Cormio et al., 2009). The risk of postoperative ED can be minimized by limiting trauma to the cavernosal tissue, thereby maintaining the veno-occlusive mechanism between the corpora cavernosa, the tunica albuginea, and the graft.

Successful straightening following PIG and PEG has been shown in 63%–100% with patient satisfaction in 41%–96% (Taylor and Levine, 2008). Recurrence depends on the type of graft material that is used and ranges from 0% to 16% (Cormio et al., 2009; Usta et al., 2003). Shortening has been reported in 0%–40% and can be minimized with the use of penile traction devices postoperatively. Finally, diminished penile sensation has been described in 0%–16% and likely results from injury to the dorsal nerve bundle (Usta et al., 2003; Licht and Lewis, 1997; Montorsi et al., 2000).

Postoperative management

Diligent postoperative rehabilitation can optimize surgical outcomes by reducing the risk of further penile shortening, recurrent curvature, and development of ED. Massage and stretch therapy can be started 2 weeks postoperatively. The patient grasps the penis by the glans, places it on gentle stretch, and massages the penile shaft twice daily for 5 minutes. External penile traction devices are recommended as well to limit further penile shortening. Additionally, nightly low dose PDE5 inhibitors beginning 1 week postoperatively induce vasodilation in an effort to reduce contraction and support incorporation of the graft.

Erectile Dysfunction in PD

Concurrent ED in the setting of PD is a clear indication for placement of an inflatable penile prosthesis (Levine and Lenting, 1997; Kendirci and Hellstrom, 2004; Ralph and Minhas, 2004; Mulhall et al., 2005; Levine and Dimitriou, 2000). Multiple straightening maneuvers can be undertaken at the time of prosthesis placement (manual modeling, tunical plication, tunical incision with or without grafting). All patients are prepped via a 10 min betadine scrub followed by a chloraprep (Carefusion, San Diego, CA) finish.

Antibiotics are selected based on the AUA best practice guidelines. If there are no contraindications, vancomycin (15 mg/kg) and gentamicin (5 mg/kg) are used (Wolf et al., 2012). We prefer a penoscrotal incision in the setting of a PD but an infrapubic approach can be used as well. Blunt dissection is carried down to the corpora and the overlying attachments are dissected away. 2-0 PDS (Ethicon, Somerville, New Jersey) stay sutures are then placed into the bilateral corpora. A self retaining retractor is then placed and maintained until all components of the prosthesis are implanted. A 3 cm incision is then made in each corpus cavernosum between the stay sutures. The space is dilated with Brook's dilators (Coloplast, Humlebæk, Denmark) and measured both proximally and distally to determine the appropriately sized cylinders. After being prepared on the back table, the prosthesis is placed into the dilated corpora with the assistance of a Furlow inserter (AMS, Minnetonka, Minnesota). After closing the corporotomies, straightening maneuvers can be undertaken. These will be reviewed in the following section.

After completion of the straightening procedures, the scrotal pump and reservoir are placed. The pump is placed into a midline subdartos pouch in an anterior and dependent position. For placement of the reservoir, the external inguinal ring is identified. The Space of Retzius is entered sharply with the aid of a Jorgenson scissors. The curved scissor tips point away from the vessels, bladder, and bowel (Levine and Larsen, 2014). The space is digitally dilated, and the reservoir is placed. The tubing is connected via the connection system provided by the manufacturer. Finally, the scrotum is closed in layers and then with Dermabond (Ethicon, Somerville, New Jersey). A "mummy wrap" is placed around the penis and the Foley catheter is removed (Henry, 2009).

Manual modeling

Manual modeling is performed after placement of the cylinders and closure of the corporotomies. With the penile prosthesis inflated, shodded clamps are placed on the cylinder tubing. One finger is placed over each corporotomy, and the penis is grasped firmly. Strong gradual pressure is then applied in the direction opposite the curve. It is recommended this be held for 60–90 s, but in practice this can prove quite difficult; 30 s seems to suffice. The curvature is continually reassessed with cylinders inflated and repeated until the residual curve is <30 degrees. If a curve <30 degrees is unattainable with modeling alone, additional maneuvers can be undertaken (Levine et al., 2010).

Tunical incision

A tunical incision should be performed if residual curve after modeling exceeds 30 degrees or there is noticeable indentation. The shaft is degloved via a circumcising incision. The point of maximal curve is identified and Buck's fascia is carefully elevated in this area exposing the plaque (Levine and Dimitriou, 2000). Incision with cautery at <30 W (for the Coloplast Titan) is performed with periodic cylinder inflation and modeling to expand the tunical defect until adequate straightening and/or girth enhancement is accomplished.

Grafting

All defects over 2 cm should be grafted to minimize risk of cylinder herniation, hemotoma formation, or recurrent curvature (Levine and Dimitriou, 2000; Carson and Levine, 2014). Graft selection was reviewed above. Notably dermal grafts should not be used in this setting due to an increased risk of infection (Chun et al., 2001). The graft is generously sized to the defect and secured in place with 4-0 PDS suture (Ethicon, Somerville, New Jersey). Recently, equine collagen fleece patch grafts (TachoSil, Baxter) have been reported, which are adhesive and therefore no suturing is needed.

Tunical plication prior to prosthesis placement

It should be noted that plication prior to (but during the same operation) inflatable prosthesis placement has been reported. This is ideal for dorsal curves and is performed via a penoscrotal incision. The plication sutures can be placed as described above. Once adequate straightening has been achieved, an inflatable penile prosthesis can be placed via the same penoscrotal incision (Chung et al., 2014).

Outcomes

Management of PD and ED via placement of a penile prosthesis and subsequent straightening maneuvers yields a high satisfaction rate. In a study out of the authors' institution, 84% of patients were satisfied with their treatment after undergoing: IPP placement alone (4%), IPP with modeling (79%), tunical incision (4%), or tunical incision and grafting (12%). The goal of surgery, regardless of the approach, is functional straightness which is defined as an erection which is both rigid and straight enough to participate in penetrative sexual intercourse. Patient counseling is paramount in communicating this goal to the patient (Levine et al., 2010).

The most common complaint associated with penile prosthesis placement (and the majority of surgeries performed on the penis) is loss of length. This concern, however, can be exacerbated in PD patients as many men have already lost length due to the underlying disease process (Montague, 2007). This has been successfully countered with the use of traction therapy. When used for 3–4 hours per day for 3–4 months prior to prosthesis placement, patients were able to at least maintain their preoperative penile length. Some men gained up to 2 cm of length using this regimen (Levine and Rybak, 2011).

Overview and Initial Diagnosis

Understanding Differences of Sex Development

Disorders of sex development (DSD), previously known as intersex conditions, are broadly defined as “congenital conditions in which development of chromosomal, gonadal, or anatomical sex is atypical (Lee et al., 2006).” This encompasses a heterogeneous group of conditions such as congenital adrenal hyperplasia (CAH), mixed gonadal dysgenesis, and androgen insensitivity syndromes but even broader definitions may include proximal forms hypospadias. Classification of DSD has evolved over the years; some terms regarding the gonadal morphology have persisted, such as mixed gonadal dysgenesis, while others have changed (see Fig. 1). Current classification includes: sex chromosome DSD (also known as disorders of gonadal differentiation), ovotesticular DSD (formerly known as true hermaphrodite), 46, XY DSD (undermasculinized males) and 46, XX DSD (masculinized females) (Hughes et al., 2006). These terms, and the term DSD itself, are under much scrutiny. Recent studies have shown that patients and families affected by these conditions have negative views of commonly used DSD terminology (Johnson et al., 2017b). In this section, DSD will be considered as *differences* of sex development, rather than disorders. While terminology continues to evolve, it is essential to discuss with patients and families their preferred terminology, and to use this not only in discussions with the family, but in the medical record, if possible (Table 1).

Initial Diagnosis

The initial work-up of DSD is often triggered in the nursery or neonatal ICU when a neonate is noted to have ambiguous genitalia. Genitalia may be overtly ambiguous or findings may be more subtle, such as clitoromegaly, posterior labial fusion, inguinal mass in a female, nonpalpable testis or perineal hypospadias. Later presentations may include primary amenorrhea in a female. In the

Fig. 1 Comparison of undifferentiated, differentiated and DSD external genitalia.

Table 1 Current nomenclature of disorders of sex development (DSD)

Current	Previous
Disorders of sex development (DSD)	Intersex
46,XY DSD	Male pseudohermaphrodite
	Undervirilized XY male
	Undermasculinized XY male
46,XX DSD	Female pseudohermaphrodite
	Overvirilized XX female
	Masculinized XX female
Ovotesticular DSD	True hermaphrodite
Sex chromosome DSD	Sex chromosome mosaicism, Gonadal dysgenesis

Adapted from Hughes, I. A., Houk, C., Ahmed, S. F., Lee, P. A. and Lawson Wilkins Pediatric Endocrine Society/European Society For Pediatric Endocrinology Consensus, G. 2006. Consensus statement on management of intersex disorders. *Journal of Pediatric Urology*, 2, 148–62.

neonatal period, gender assignment, and use of gender specific pronouns should be avoided until a decision is made as to the sex of rearing. Currently, it is recommended that the multidisciplinary team, in close collaboration with the family, should strive for eventual gender assignment (Lee et al., 2006; Lee et al., 2016). Though it should be recognized and discussed that some families may opt to not assign a binary gender. At all times during the work-up and management of DSD, open communication is essential. Participation by the family should be actively encouraged and all concerns should be respected and addressed.

Evaluation of a neonate

Once a patient with potential DSD is identified, a multidisciplinary team should be assembled to assist with the diagnosis and management. The team should include the primary care service, endocrinology, urology, surgery or gynecology, genetics, and social services or psychology. If available, or when the situation demands, ethics should also be involved. The role of nursing staff as part of the team should not be undervalued as they spend more time with the family and may have insight other team members do not. As always, evaluation should begin with a comprehensive history. This includes a detailed prenatal and family history, as such DSD are heritable.

Physical examination

When possible, physical exam should be performed with as many members of the team as possible to prevent repeat physical and psychological trauma to the patient and family. Photography may be helpful in preventing repeated exams and to evaluate changes in response to therapy. In newer electronic medical records, photographs can be included in the patient chart.

Assessment of the external genitalia should document the size and structure of the genital tubercle (also known as the clitorophallic structure), the location of the urethral opening, the morphology of the labioscrotal folds, ano-genital distance, as well as presence and location of gonads (see Fig. 1). The genital tubercle is the undifferentiated structure that develops into either the penis in a male or the clitoris in a female (Martinez-Mora, 1994). Evaluation should include the size (in stretched length and width), the length, width, and shape of the glans, as well as depth of the urethral groove (Malone et al., 2012). Any curvature should also be recorded. The shape and position of the urethral meatus, or the opening of the urethra, should be noted. In hypospadias, the meatus may located on glans, shaft or perineum (Lee et al., 2016). This is discussed further in detail in the masculinizing surgery section. The labioscrotal folds, which may be referred to as the genital folds, should be assessed for symmetry, fusion, pigmentation, and rugation. They should also be palpated for presence of gonads. Any other physical abnormalities unrelated to the external genitalia should also be evaluated, such as abnormal facies. This baseline examine is essential to initial diagnosis as well as future surgical planning.

Laboratory evaluation

Laboratory evaluation should be done in close consultation with endocrinology. A karyotype should be sent when DSD is suspected; though this will typically take a few days to result. Together, physical examination and karyotype may suggest a diagnostic classification, but other testing may be necessary. Electrolytes should be obtained immediately as salt-wasting CAH can be an emergency. CAH is a group of autosomal recessive conditions in which there is an enzymatic mutation in the steroid synthesis pathway (see Box 1). Testosterone, dihydrotestosterone and 17-hydroxyprogesterone should also be measured. Elevated 17-hydroxyprogesterone in a neonate is pathognomonic for CAH (Table 2).

Gonadotropin levels (follicle stimulating hormone [FSH] and luteinizing hormone [LH]) should also be measured, in addition to anti-Müllerian hormone (AMH, also known as Müllerian inhibiting substance [MIS]). While AMH is secreted in small amounts from ovarian granulosa cells and present in girls, circulating concentrations are much higher in boys and are suggestive of male gender. AMH is secreted by the Sertoli cells of the testis and confirms presence of testicular tissue, even in the absence of palpable gonads. FSH and LH should be normal or slightly elevated in steroid synthesis disorders, such as CAH, or androgen insensitivity but will be markedly elevated in sex chromosome DSD with dysgenetic gonads, such as Turner or Klinefelter

Box 1 Congenital adrenal hyperplasia (CAH)

Inheritance	Autosomal recessive
Etiology	Gene mutation in enzymes of the steroid synthesis pathway (most common mutation: 21-hydroxylase)
Symptoms	Vary based on which enzyme is mutated and thus which steroid is deficient or in excess Lack of mineralocorticoids: salt-wasting, dehydration, vomiting Lack of androgens/estrogens: ambiguous genitalia, undermasculinization in males, infertility in females Excess androgens: ambiguous genitalia, overmasculinization in females, precocious puberty, infertility
Diagnosis	Serum electrolytes, Serum 17 α -hydroxyprogesterone (newborn screen), Adrenocorticotrophic hormone (ACTH) stimulation test

Table 2 DSD diagnoses by classification

<i>Sex Chromosome DSD</i>	<i>46,XX DSD</i>	<i>46,XY DSD</i>
45,X (Turner Syndrome)	Disorders of Ovarian Development Ovotesticular DSD Testicular DSD <i>SRY</i> ⁺ <i>SOX9</i> Duplication Gonadal Dysgenesis	Disorders of Testicular Development Complete gonadal dysgenesis (Swyer syndrome) Partial gonadal dysgenesis Gonadal regression Ovotesticular DSD

Syndromes (Lee et al., 2016). If the diagnosis is still not clear from initial testing, further analysis may be required with human chorionic gonadotropin (hCG) or adrenocorticotrophic hormone (ACTH) stimulation testing. This should be done in close collaboration with an endocrinologist. Though not first line testing, complete genetic sequencing can be useful to identify specific genes associated with DSD and to reveal Y-chromosome material not assessed by conventional karyotyping. It is important to assess the presence of Y-chromosome material, as this increases the risk of gonadoblastoma in female patients with Turner Syndrome or mixed gonadal dysgenesis (MGD). This may be done with polymerase chain reaction (PCR) testing. In some cases, despite thorough physical exam and laboratory evaluation, the specific diagnosis may remain unclear.

Imaging

Ultrasound is the mainstay of radiologic imaging in the evaluation of DSD. This both avoids the radiation of computerized tomography (CT) and the anesthesia required in neonates to undergo magnetic resonance imaging (MRI). Ultrasound allows for visualization of gonads and assessment of Müllerian structures, such as the uterus and Fallopian tubes. It further allows for evaluation of the kidneys and adrenal glands, as these may be affected in conditions such as Turner Syndrome. If ultrasound is non-diagnostic, MRI may be necessary to further delineate the anatomy. Historically, genitograms, or fluoroscopic studies of the uro-genital system were performed; however these are no longer routine as endoscopic evaluation is far more helpful in defining the anatomy (Vanderbrink et al., 2010). Endoscopy allows for an understanding of internal structures in relation to one another and may assist in surgical planning. In select cases, laparoscopy may also be required to identify and evaluate internal structures. This also has the advantage of allowing for gonadal biopsy, which may be necessary for final diagnosis.

Evaluation of an adolescent

Though most cases of DSD are recognized in the neonatal period, some may not be detected until the time of expected puberty as they are not associated with ambiguous genitalia. The most common presentation is primary amenorrhea in a female. Patients with complete androgen insensitivity syndrome (CAIS) often present in this fashion (see **Box 2**). As with neonates, a detailed history and physical is essential to evaluation of the adolescent with suspected DSD. Adolescence is a time of change and the psychosocial needs of the patient should be considered and respected. History should include developmental history, including milestones and learning disabilities as well as any menstrual history in females, including cyclic abdominal pain. Physical examination should include evaluation of external genitalia as well as that of secondary sexual characteristics such as breast development and hair growth patterns. Some diagnosis, such as Turner syndrome and Klinefelter may be suspected on the basis of physical examination alone (see **Box 3**). Though a comprehensive discussion of all DSD is beyond the scope of this chapter, a list of the most common DSD can be found in **Table 3**.

Surgical Considerations

Controversy Regarding the Timing of Surgical Management

Gender assignment must be done with great care as it may have irreversible psychosocial consequences for the patient. As previously discussed, gender assignment should be done in conjunction with a multi-disciplinary team assessment and open discussion with

Box 2 Androgen insensitivity syndromes

	Complete androgen insensitivity syndrome (CAIS) Affects only 46,XY males; 46,XX females are minimally affected Most common cause of 46,XY DSD (undermasculinized male)	Partial androgen insensitivity syndrome (PAIS)
Inheritance	X-linked recessive	X-linked recessive
Etiology	Complete inability of cells to respond to androgens due to mutation in androgen receptor	Partial inability of cells to respond to androgens due to mutation in androgen receptor

the family regarding the pros and cons of gender assignment (male, female and unassigned). Regardless of gender assignment, parents need to be aware of the risk of gender dysphoria later in life and the small possibility of gender conversion (Chowdhury et al., 2015; Reiner and Kropp, 2004). Once gender has been assigned, additional discussion of possible surgical management and reconstructive treatment can be undertaken. The aims of surgery are to restore functional genital anatomy for future penetrative intercourse and reproduction, if possible, reduce the risk of gonadal cancer, foster development of individual identity, avoid stigmatization due to atypical anatomy (Mouriquand et al., 2016).

Historically, early surgical treatment was pursued to “normalize” children with ambiguous genitalia. However, today there is increased advocacy against early surgery so as to allow children to participate in the decision making process. The guiding surgical principle is to avoid early irreversible surgery, especially when the assigned gender may be controversial. On the other hand, patients with a diagnosis such as CAH have been shown to have very high rates of female gender identity and low rates of gender dysphoria in adulthood (Binet et al., 2016). As such, many would agree with proceeding with early surgery for many forms of CAH. While delaying irreversible surgical procedures does preserve the child’s autonomy, this decision is not without difficulty for the patient and family. Though lessening in the era of transgender and DSD advocacy, there is still significant societal pressure to fall into the binary norm of either male or female. A child raised to be different in this way may have trouble fitting in at school and in sports. The family will also be subject to psychosocial stressors associated with having a child who is different. At present, there is limited data on the impact of raising a child as neither male nor female (Rangecroft, 2003). As there is little evidence regarding the long-term outcomes of children who do not undergo early surgery, it is imperative to openly discuss this controversy with families.

Preoperative Preparation

Once the decision has been made to proceed with surgery, regardless of timing, the patient must be appropriately prepared for surgery. Patients with endocrine aberrations should be seen by the endocrinology service for metabolic stabilization. They may require peri-operative stress dose steroids. For complex cases, anesthesia should be involved in early preoperative planning. If the child is old enough to understand the implications of surgery, technical aspects should be explained at the appropriate level and assent obtained. Support staff, such as child life, should also be utilized throughout the peri-operative process. The psychosocial stressors of the diagnosis and of the surgery must be kept in mind and psychological services should play a central role for both the patient and the family.

Antibiotics should be given based on the procedure. Typically in the cases of laparoscopy or orchiopexy, single dose antibiotics to cover skin flora are given. In cases of feminizing genitoplasty with vaginoplasty, broad spectrum antibiotics are given for several days peri-operatively and the patient may need a mechanical bowel preparation with either an enema or an osmotic agent such as GoLyte[®]. Antibiotic use for hypospadias repair is being studied and is an issue of ongoing debate (Faasse et al., 2017). There is less standardization of antibiotic prophylaxis for genitoplasty and considerations should be given to prior history of urinary tract infection, asymptomatic positive cultures and local antibiotic resistance patterns.

Masculinization Surgery (Hypospadias Repair)

In cases of DSD, masculinization surgery primarily entails hypospadias repair and orchiopexy. Orchiopexy has been well described elsewhere. Hypospadias is a condition in which the urethral meatus is located proximal to the normal location at the tip of the glans. It is often associated with some degree of ventral curvature, known as chordee. The urethral meatus can be located anywhere from the glans, to the perineum. In general, the most distal the meatus, the lesser degree of chordee, and the more proximal the meatus, the greater the degree of chordee. In DSD, proximal hypospadias is more common. The meatus is located somewhere along the proximal shaft, peno-scrotal junction or perineum and is associated with functional problems, such as inability to void standing up and inability to have penetrative sexual intercourse. Proximal hypospadias is technically more challenging to repair than distal hypospadias. Goals of hypospadias repair are a straight penis, good sexual function, the ability to stand to void, a satisfied *adult* patient and parent. Ideally, there will be a slit-like meatus on the glans, a cone shaped glans with a well defined coronal sulcus, no penile curvature, as well as an appropriate anatomic relationship between the penis and the scrotum.

Surgical considerations

Proximal hypospadias is technically more challenging than distal hypospadias repair as tissues are underdeveloped and more dysplastic, especially in cases of DSD. Various techniques have evolved over the years. Though somewhat debated, the timing of hypospadias repair is far less controversial than feminizing genitoplasty. Most surgeons recommend repair between 6 and 18 months of age, in line with recommendations (American Academy of Pediatrics, 1996).

As with other complex surgical procedures, high volume surgeons and centers have been associated with better outcomes (Chowdhury et al., 2007). Patients should be referred to appropriate tertiary care centers for management of hypospadias in the context of DSD. There is no standard surgical procedure for proximal hypospadias repair. Many authors use preoperative testosterone to increase the size of the glans and vascularity of the penile tissue. Some studies have shown improved outcomes with use of testosterone; while others have shown increased rates of complications as testosterone has been associated prolonged wound healing (Kaya et al., 2008; Wright et al., 2013). Other work has suggested that boys with proximal hypospadias may have relative androgen resistance, limiting the utility of testosterone supplementation (Snodgrass et al., 2014). The use of testosterone supplementation in proximal hypospadias repair remains controversial and is left to the discretion of the surgeon and family.

Historically, two-stage repairs were recommended for proximal hypospadias. Then, in the 1980s, the single stage repair was shown to be feasible with acceptable results. However, over the past 10–20 years many surgeons reintroduced two-stage repairs to due to suboptimal short-and long-term results with the one stage repair (Gong and Cheng, 2017). Complications include suboptimal cosmesis, early wound breakdown and dehiscence, urethral stricture, diverticulum or fistula formation. Late complications such as recurrent chordee, urethral stricture and p erectile dysfunction are also well documented. As such, the two-stage repair is in vogue once again.

Surgical technique

While there is no standard technique for proximal hypospadias, most experts would agree that surgeons can consider a single stage repair in cases where chordee is <30 degrees and there is a healthy urethral plate (Gong and Cheng, 2017). However, in most cases of DSD with proximal hypospadias, the severity of the curvature will require a two-stage repair.

The procedure begins with a circumcising incision around the dorsal and lateral surfaces of the penile shaft and then a U-shaped ventral incision to the proximal aspect of the meatus (Gong and Cheng, 2017). Chordee is released by degloving the penis just above Buck's fascia. Residual curvature is then assessed. If residual chordee is <30 degrees dorsal plication usually suffices, but if residual chordee is >30 degrees the urethral plate will need to be divided. Transverse incisions of the corporal body (also known as fairy cuts) can be attempted, but if curvature persists corporal body grafting may be required. Small intestine submucosa is commonly used as graft material (Kropp et al., 2002). Once chordee has been addressed, a decision must be made as to how to create the neourethra. Skin flap or grafts, or buccal mucosa may be used. These grafts or flaps are used to cover the urethral defect on the ventral surface of the shaft and form the new urethral plate. This new urethral plate is left open and allowed to heal. The patient continues to void from the proximally located meatus. At the second stage, this newly vascularized urethral plate will be tubularized to create a single continuous urethra. The second stage typically occurs six or more months later (Gong and Cheng, 2017). Once the urethra has been tubularized, typically in two layers, a vascularized flap is placed over it, either from the dartos of the penis or the tunica vaginalis of the testis. This skin is then closed over this layer.

Feminization Surgery (Feminizing Genitoplasty)

Feminization surgery, commonly known as feminizing genitoplasty, consists of clitoroplasty, vaginoplasty and labioplasty. These procedures may be done individual, or together in one combined procedure.

Timing

Discussions as to timing of feminizing genitoplasty are rife with controversy. Though many in the medical community support early genitoplasty, there are those who universally oppose all gender surgery on legal and ethical grounds (Diamond and Garland, 2014). Opponents of early surgery focus on the principle of autonomy and the legal rights of the patient to make his or her decision regarding his or her body. On the other hand, in a case-control study of patients and parents involved in infant feminizing genitoplasty for CAH, nearly 90% of patients and 100% of parents support early surgery (Binet et al., 2016). Another retrospective study has shown that, despite some difficulties with sexual function, patients mostly preferred early surgery (Fagerholm et al., 2011).

Individuals that support early clitoroplasty express concern that girls who have not undergone surgery and have clitoromegaly may feel embarrassed or be made fun of in the changing room and this could lead to social withdrawal (Creighton et al., 2012). Often, the decision for early clitoroplasty is driven by the parents and their desire for a “normal” appearance of the external genitalia. This highlights the need for a multidisciplinary team that can offer not only the scientific rationale, but also the social support required to make the best decision for the child. The timing of vaginoplasty is also controversial. Proponents of early vaginoplasty offer the tangible benefits of using urogenital sinus mucosa for infant genitoplasty (Creighton et al., 2012). If the urogenital sinus is closed without concomitant creation of a vagina, this mucosa may not be available for use later. Similarly, if infant clitoroplasty is performed and vaginoplasty is not done at the same time, the clitoral foreskin is lost. The clitoral foreskin is a key component of an inversion vaginoplasty. However, the vagina is nonfunctional in childhood and delaying vaginoplasty allows the child to be involved not only in the decision making process but also the pre and post-operative care. This is especially important as vaginal dilation is necessary postoperatively and cannot be done without the willing participation of the child. Further follow-up is needed to elucidate long-term cosmetic and functional results as well as sexual satisfaction of feminizing genitoplasty.

Technique

Clitoroplasty

The goal of clitoroplasty is to reduce the size of the genital tubercle to give a feminine appearance without compromising future sexual function. Since some forms of reduction clitoroplasty carry the risk of decreased genital sensation, consensus guidelines recommend against clitoroplasty in the cases of mild virilization, reserving the procedure for more severe virilization, typically done in conjunction with vaginoplasty (Lee et al., 2006). As with other genitoplasty procedures, there is much controversy as to the optimal technique for reduction and anchoring of the genital tubercle.

Typically, the clitoris is degloved and the clitoral foreskin divided vertically to be reconstructed into the labia minora. This can be done as a Y-V plasty. Care is taken not to injure the dorsal neurovascular bundles as these provide sensation to the clitoris. The clitoris is reduced in size by excising the distal erectile tissue through ventral incisions on the corpora, without excising the corporal body and tunica albuginea itself. The glans tissue is then recessed under the pubic bone. A recent modification has been proposed in

which the corpora are divided from one and other and each corpus is then rotated inferior and laterally to be hidden beneath the labial folds (Pippi Salle et al., 2007). This allows for preservation of the corpora in the case of desired reversal of surgery in the future.

Vaginoplasty

Vaginoplasty techniques vary greatly as the anatomy and relationships of the vagina and urethra vary. The goal of vaginoplasty is to create a vagina suitable for sexual intercourse as well as to allow for unobstructed menstruation. In cases of DSD, there may not be two distinct openings for the urethra and vagina on the perineum, instead there is a common channel with a single opening on the perineum. The common channel is the fused urethra and vagina, though the bladder and uterus remain separate. Anatomy in which the vagina and urethra are separate until the very distal aspect near the introitus is known as a low confluence urogenital sinus. By contrast, in a high confluence sinus, the urethra and vagina form one common channel until a proximal location near the bladder and cervix. Low confluences sinuses are technically easier to repair. In high confluence sinuses, urinary continence becomes a concern, as the length of the vagina from the common channel is closely related to the bladder neck continence mechanism.

The rationale for early surgery is that tissues are more amenable to mobilization, there is decreased surgical morbidity and the child tolerates the surgery with less psychosocial trauma, as they often do not remember the surgery later in life. However, high rates of vaginal stenosis are associated with early surgery, as vaginal dilation is not appropriate in the infant period. Those that advocate for later surgery cite lower rates of stenosis as vaginal dilation can be performed, but tissues are harder to mobilize later in life and surgery may be associated with higher morbidity. Surgeons should discuss with the family realistic expectations for early versus delayed surgery (Alizai et al., 1999).

Due to the technical challenge of these surgical repairs, several techniques have emerged. While there is no consensus as to which is the optimal repair, total and partial urogenital sinus mobilization have become common in past few decades and have largely replaced flap vaginoplasties (Braga et al., 2006). Elucidation of specific techniques is beyond the scope of this chapter but a brief comparison is provided below. In total urogenital mobilization surgery, the urethral-vaginal confluence is mobilized as a single unit all the way down to provide two separate perineal openings. In comparison, partial urogenital mobilization preserves the pubo-urethral ligament and has been posited to improve long term continence (Rink et al., 2006). In cases of a high confluence, where the urethral-vaginal confluence will not reach the perineum the vagina can be mobilized off the urogenital sinus and down to the perineum (Creighton et al., 2012; Salle et al., 2012). In very severe cases, the vagina can be approached posteriorly, by opening the anterior wall of the rectum; this is known as the anterior sagittal transrectal approach (ASTRA) and is done in prone positioning.

Labioplasty

Labioplasty may be done at the time of clitoroplasty or at the time of vaginoplasty. The rugated, fused scrotal skin is used to construct the labia majora (Creighton et al., 2012). The labia minora are constructed from the clitoral foreskin as described above.

Gonadal Surgery

Another increasingly controversial issue is the fate of the gonads. Historically, patients at risk for germ cell tumors underwent prophylactic gonadectomy but as a more nuanced understanding of malignancy risk and fertility potential has emerged, this paradigm is being challenged. Gonadal surgery is now being delayed or altogether deferred (Spoon et al., 2017). Prior to a discussion of gonadal surgery there must be an understanding of the current state of fertility potential and malignancy risk for patients with DSD.

Fertility potential

Only 14% self-identified DSD patients have children, as compared to 40% of their counterparts in the same age group (Slowikowska-Hilczek et al., 2017; Fleming, 2016). Rates of fertility, and fertility potential, vary by DSD. Infertility, or decreased fertility potential, in patients with DSD may be multifactorial (see Table 3). Patients with DSD have not only abnormal gonadal development, but also an abnormal hormonal milieu (Finlayson et al., 2016a). This leads to impaired gamete production and high rates of early gonadal failure. Due to increased risk of malignancy in certain DSD, many patients may be candidates to undergo gonadectomy. This itself is an iatrogenic cause of infertility, as potential gametes are removed. There may also be assumed infertility due to discordance between assigned gender and gonadal type (Finlayson et al., 2016a). Educating pubertal and postpubertal patients as to their unique external and internal genitalia is critical to an understanding of sexuality and fertility. Potential for fertility must be considered in light of the particular diagnosis, the severity of the hormonal imbalances as well as prior surgical or hormonal treatment. Fertility potential for some DSD conditions are discussed below.

Rates of fertility in CAH vary by gender. Women with severe, salt-wasting forms of CAH have been reported to have rates of fertility ranging from 0% to 10% whereas women with simple masculinizing forms have been reported at 33%–50% (Van Batavia and Kolon, 2016). Other studies have shown that glucocorticoid treatment improves rates of fertility in CAH females (Bidet et al., 2010). Conversely, approximately 50% of males with CAH are fertile.

Rates of fertility may vary by assigned gender and fertility potential may change as a result of prior treatments and therapies. Females with partial androgen insensitivity (PAIS) typically undergo gonadectomy, and thus loss of fertility potential. Whereas if they are raised male, they receive hormonal treatment and maintain their fertility potential. Women with CAIS have limited

natural fertility potential as they lack Müllerian structures. Patients with 5-alpha reductase deficiency reared as male may have potential fertility through the use of TESE and ICSI but those raised as female have no fertility potential as they lack internal female genitalia (Van Batavia and Kolon, 2016).

Fertility potential in sex chromosome DSD is complex and often dependent on the particular histology of the gonads at a given point in time. Patients with Turner and Klinefelter syndrome undergo progressive gonadal failure, but do have functional tissue and have been shown to have spontaneous conception, albeit at low rates (Slowikowska-Hilczer et al., 2017; Kathrins and Kolon, 2016). Similarly, a patient with ovotesticular DSD may have functional oocytes and thus the potential for reproduction using assisted reproductive technology (ART) (Slowikowska-Hilczer et al., 2017). Biopsies may help to guide discussions of fertility potential in certain patients. Realistic expectations regarding future fertility should be provided to parents prior to gender assignment as this may affect their decision in gender rearing.

Information regarding potential fertility should be discussed with families in light of current reproductive technology. However, as technology advances, options for fertility preservation may evolve and this too should be discussed. Previously it was felt that patients with dysgenetic gonads did not have fertility potential. More recent analysis of gonads and biopsy specimens has shown presence of viable germ cells in ovotestes, dysgenetic testis and even 15% of streak gonads (Finlayson et al., 2016a). These viable germ cells decline with age and as such, fertility potential may be lost if early preservation is not undertaken. At this time, cryopreservation of sperm, oocytes and even embryos is well-established for postpubertal patients, but work is underway to mature prepubertal gonocytes in vitro for future use (Johnson et al., 2017a). Working with clinicians in OncoFertility—a field combining oncology and reproductive medicine to improve the reproductive future of cancer survivors—who are well-versed in fertility preservation is critical for advancing the field of fertility preservation in DSD (Finlayson et al., 2016b). As technologies are being developed, open communication with families about current and future possibilities for fertility is crucial.

Risk of malignancy

Malignancy potential is also an important consideration in discussing gonadal surgery. As with fertility potential, the risk of malignancy varies by diagnosis. DSD patients can be at risk for gonadoblastoma, germ cell tumors such as seminoma, nonseminoma, as well as carcinoma in situ, now called germ cell neoplasia in situ (GCNIS), though the risk may be lower than once presumed. The risk of germ cell tumors is linked to the presence of Y chromosomal material, particularly the testis specific protein (TSPY) (Wolffenbuttel et al., 2016; Cools et al., 2011). Other markers such as octamer binding protein (Oct 3/4), a transcription factor, and cKIT ligand, have also been linked to germ cell malignancies (Wolffenbuttel et al., 2016; Kathrins and Kolon, 2016). As such karyotyping, fluorescence in situ hybridization (FISH) and immunohistochemical analysis may be required to accurately gauge and discuss malignancy potential. Judicious use of open and percutaneous biopsies may improve the assessment of the risk of malignancy by providing tissue for diagnosis and staining. Malignancy potential for some DSD are discussed below.

Risk of malignancy in DSD varies by diagnosis. Gonadoblastoma is estimated to occur in 7%–10% of women with Turner Syndrome and known Y chromosomal material (Gravholt et al., 2000). Traditionally, men with Klinefelter were thought to be at increased risk of seminoma, but newer evidence suggests that this may not be true, with two studies reporting no Klinefelter patients with testicular cancer (Accardo et al., 2015; Swerdlow et al., 2005). In CAIS, risk of malignancy has been reported to be 0.8%; whereas females with PAIS have a 15% risk (Pleskacova et al., 2010). Increased awareness of these rates of malignancy has changed the paradigm around gonadal surgery for these DSD. Previously in cases of CAIS, gonadectomy was done early in life, but it has since been realized that these functional gonads carry a low risk of malignancy. This, coupled with the benefit of providing an adequate hormonal milieu for spontaneous puberty, has led some to delay gonadectomy until after puberty, if not defer it altogether. Conversely, as females with PAIS are at a greater risk of malignancy early gonadectomy is still recommended. Research into the risk of malignancy allows for more informed and shared decision making by the patient and family.

All DSD are not linked to risk of germ cell tumors. Some patients, such as females with congenital adrenal hyperplasia, are not at increased risk of gonadal malignancy, as they have two normal ovaries, and no gonadal surgery is recommended or required. Males with CAH are at risk of testicular or paratesticular adrenal rests if hormone supplementation is inadequate but these “tumors” are nonmalignant and regress with appropriate treatment (Kathrins and Kolon, 2016). Discussion of the risk of malignancy of a particular DSD should be based on current epidemiologic data and individual histology, if available, to allow for decision making regarding early or deferred gonadal surgery.

Surgical considerations

While perhaps operatively less complex than hypospadias repair or feminizing genitoplasty, gonadal surgery has become increasingly intellectually challenging as new technology evolves regarding potential fertility preservation and new data emerges on the specific risk of malignancy potential. Where an ovotestis may have once been removed, a patient must now consider her 2.6% risk of malignancy against the very real possibility that she has functional oocytes and could have a child through ART (Slowikowska-Hilczer et al., 2017; Pleskacova et al., 2010). Decisions regarding gonadal surgery, particularly gonadectomy, pertain to both patients identified as male and those identified as female. The aim of gonadal surgery was once to prevent malignancy, but now gonadal function and fertility are of increasing importance. Furthermore, the importance of hormone production from gonads, even if discordant with the gender of rearing, should not be overlooked, as these promote growth, bone health and puberty.

Conclusion

DSD is a heterogeneous group of conditions in which chromosomal, gonadal or anatomical sex development is atypical. Management of DSD should be undertaken in a multidisciplinary, patient centered team with the goal of shared decision-making. Surgical considerations must be made in light of fertility and malignancy potential as well as the patient and families goals and desires. Further research continues as to optimizing surgical techniques and maximizing future fertility in these patients.

Surgical Reassignment From Female to Male

Ervin Kocjancic, University of Illinois Hospital and Health Science System, Chicago, IL, United States

Valerio Iacovelli, University of Rome Tor Vergata, Rome, Italy

Introduction

Gender dysphoria (GD; *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition) is characterized by a marked discrepancy between one's birth-assigned sex and one's gender identity and expression and is associated with immense bodily and emotional distress (Gooren, 2011). Some people with this condition, in order to manage the discrepancy or imbalance they experience, desire to possess the secondary sexual characteristics of the opposite sex (Brown, 1990). Not all transgender persons have gender dysphoria. For those who do, medical and surgical therapy can play a pivotal role in relieving their psychological discomfort (Monstrey et al., 2001; Imbimbo et al., 2009; Vujovic et al., 2009).

Gender reassignment surgery is indicated for the treatment of gender dysphoria. Patients who suffer gender dysphoria feel that their birth gender is somehow “wrong” and seek to adopt the opposite gender role. To facilitate this change, many patients seek surgery so that their bodies resemble their chosen gender. Gender reassignment surgery refers to all surgical procedures that a patient wishes to receive to resemble the appearance of the opposite gender. Sex reassignment surgery is part of gender reassignment surgery and refers only to the reconstruction of the genital area.

Currently, the guidelines on gender reassignment are published by the World Professional Association for Transgender Health (WPATH), and the standards of care are updated regularly and available for download from the WPATH website (World Professional Association, 2015a, b).

Epidemiology

Although early estimates on the prevalence of gender dysphoria were focused on identification of individuals for gender confirmation surgery, it was later realized that some individuals neither desired, nor were candidates for, such surgery (Kockott and Fahrner, 1987).

Early estimates of the prevalence of transsexualism were 1 in 37,000 biological males and 1 in 107,000 biological females (Roberto, 1983). Interestingly, approximately three times as many biological males as compared with biological females sought genital surgery. This historical discrepancy may exist for multiple reasons, including less accessibility, and more complicated—and expensive—surgical options available for biological females. However, there has been an increase in the number of biological females seeking genital surgery. More recent data estimate that 1 in 11,900 adult biological males and 1 in 30,400 adult biological females undergo genital procedures (PJ et al., 1996).

The true prevalence of gender dysphoria is likely much greater than these early estimates. With increased advocacy, acceptance, and access to care, individuals are now able to seek medical attention in an atmosphere free from harassment or shame.

Etiology

The cause of gender dysphoria remains unknown (Ettner, 2007). Research has investigated genetics, hormonal influences, family dynamics, and psychoanalytical observations as possible contributing causes (Selvaggi and Bellringer, 2011).

Existing theories on the pathogenesis of the disorder were based mainly on psychological perspectives, without supportive evidence based data (Selvaggi and Bellringer, 2011). These theories mainly focused on the role of nurture (environmental and external psychological factors) as the cause of gender identity disorder. By contrast, studies from the past two decades advocate a neurological basis for gender identity with sexual morphological differentiation of the brain (Selvaggi and Bellringer, 2011; Zhou et al., 1995; Kruijver et al., 2000; Swaab et al., 2002). These researchers have found that the volume of the central subdivision of the bed nucleus of the stria terminalis—a brain area that is essential for sexual behavior—is larger in men than in women, with similar findings in transsexual individuals (FtM transsexuals have the same size in this specific brain area as their male counterparts, and vice versa) (Selvaggi and Bellringer, 2011; Zhou et al., 1995; Kruijver et al., 2000; Swaab et al., 2002). In a 2008, another sex differentiated area in the brain, the hypothalamic uncinate nucleus, was demonstrated to have a relationship with gender identity (Garcia-Falgueras and Swaab, 2008).

Most probably, the etiology of transsexualism is both biological (nature) and dependent on external psychological influence (nurture) (Selvaggi and Bellringer, 2011). Although the etiology of transsexualism remains unknown, most specialists concede that psychotherapy aimed at “adjusting the mind to the body” is not an effective treatment on its own: no demonstrable, successful conversions of transsexual persons via psychotherapy alone have been observed (Meyer et al., 2001). Most professionals concur that gender reassignment surgery, or “adjusting the body to the mind”, is the best way to assist individuals with severe gender dysphoria who desire this procedure (Cohen-Kettenis and Kuiper, 1984; Kuiper and Cohen-Kettenis, 1988).

Disease Management

Medical Therapy

Masculinizing hormone therapy is initiated to induce virilization. The effects of ongoing testosterone therapy are multiple and, most relevant to genital reconstruction, include clitoral hypertrophy. The primary hormonal treatment is a testosterone preparation.

Before initiating hormone therapy, a psychosocial assessment by a qualified mental health or medical practitioner should be performed. The goal of endocrine therapy is to change secondary sex characteristics in order to reduce gender dysphoria and/or facilitate a physical presentation consistent with the individual's sense of self. Although specific hormonal regimens may vary between centers, the surgeon should be familiar with the possible side effects of hormonal therapy and how they relate to the surgical care of the transgender patient. These possible side effects include issues related to liver function, risk of venous thromboembolism, electrolyte imbalance, drug–drug interactions.

Masculinization through hormonal therapy for transmen follows general principles of hormone replacement for treatment of male hypogonadism. Both intramuscular and transdermal testosterone preparations are available and may be used to achieve testosterone values in the normal male range (typically 400–1000 ng/mL) (Hembree et al., 2009).

Complete blood count (CBC) and liver function level should be monitored because testosterone therapy can result in erythrocytosis and elevation in liver enzymes. Other risks of testosterone therapy include hypertension, excessive weight gain, salt retention, lipid changes, cystic acne, and adverse psychological changes (Hembree et al., 2009).

Preoperatively, transmen should discontinue their testosterone 2 weeks before gender confirmation surgery. Testosterone can be converted to estradiol in adipose tissue by the aromatase enzyme and this could augment the risk of postoperative venous thromboembolism.

Patients should not restart their testosterone therapy until they are ambulatory after surgery (Schechter, 2017).

Surgical Therapy

The World Professional Association for Transgender Health recommends that female-to-male transgender genital reconstruction proceed in accordance with the following criteria: “[if] persistent gender dysphoria is documented, [if] the patient has capacity to make informed consent [and] has reached legal age (if younger follow the standard of care for children and adolescents), [if] significant medical or mental health concerns are present they must be well controlled, [if] the patient has undergone 12 continuous months of hormone therapy (unless there is a medical contraindication or the patient is unwilling), and [if] the patient has lived continuously for at least 12 months in the gender role that is congruent with their gender identity” (Selvaggi et al., 2012).

Surgical procedures for the natal female subject being affirmed as a male subject (hereto referred to as female-to-male FtM transgender surgery) can be divided in genital reconstruction (bottom surgery), often paired with a combination of other hormonal and surgical interventions (e.g., urethroplasty, hysterectomy, oophorectomy) and male chest contouring (nongenital surgery or “top surgery”) and facial feminization (Frey et al., 2017).

Nongenital Surgery (Schechter, 2017; Frey et al., 2017)

Chest surgery

The chest wall is the main area in which additional surgery may be required, as the possession of female breasts all but precludes satisfactory passing in male role, other than by using tight binding. This procedure, commonly performed before genital surgery, involves bilateral subcutaneous mastectomies, liposuction of the chest, and repositioning and resizing of the nipple–areola complex, when necessary. Several different techniques are used, and the choice of technique depends on the volume of breast parenchyma, degree of breast ptosis, position and size of the nipple–areola complex, and degree of skin elasticity.

Mastectomy needs to be carried out by a surgeon with wide experience in FtM mastectomy. The exact technique will depend on the volume of breast tissue, and the skin excess and elasticity (Monstrey et al., 2008). Hormone therapy is discontinued 2 weeks before surgery. Small, nonptotic breasts can often be treated with periareolar incisions (limited incision). In these cases, the nipple may be reduced by a wedge resection of the lower pole, but the areola is not repositioned. A small amount of tissue is left beneath the nipple–areola to preserve viability. Circumareolar (purse-string) or vertical incisions with free nipple–areola grafts can be used for larger breasts with mild ptosis requiring smaller amounts of skin removal. Finally, traditional transverse inframammary crease incisions (double incision) with free nipple areola grafts may better serve individuals with larger breast volumes and increased breast ptosis requiring large amounts of skin removal. Finally, the nipple itself and the diameter of the areola are often reduced. When done properly, the results may be very satisfactory, but poor technique can lead to unacceptable cosmetic results. Minor revisions to ameliorate the final cosmetic outcome are often required (Monstrey et al., 2008). Additional complications include, but are not limited to, hematoma, seroma, infection, delayed healing, loss of nipple grafts, asymmetry, and underresection and overresection of tissue leading to chest wall contour abnormalities.

Gynecology

Patients will also require hysterectomy and ovariectomy, because of the potential risk of endometrial carcinoma with protracted testosterone use, and are usually accomplished laparoscopically. However, access for the vaginal route may be limited in nulliparous patients on testosterone therapy. Most transmen undergoing genital surgery will have undergone a hysterectomy

and oophorectomy at least 3 months before either metoidioplasty or phalloplasty. The short blind-ended vagina can be left in place or removed.

Genital Surgery (Schechter, 2017; Frey et al., 2017)

The aims of FtM genital surgery are to permit micturition in a standing position, provide bulk inside underwear and swimwear for cosmetic appearance, as well as enable sexual function, with erection, and penetrative intercourse. Ideally, these aims should be achieved with preservation of genital sensation sufficient for orgasm, minimal scarring, and a good cosmetic outcome. Not all patients require all of the aims to be fulfilled; interestingly, the ability to urinate in a standing position is the most common request.

The goal of genital surgery in transmen may range from clitoral release (metoidioplasty), with or without urethral lengthening, to creation of a penis, capable of sexual penetration. Transmen undergoing genital surgery discontinue their hormone therapy 2 weeks before surgery and complete a bowel preparation the day before surgery. Before surgery, sequential compression devices are placed and intravenous antibiotics are administered. Chemoprophylaxis for venous thromboembolism is administered subcutaneously.

Metoidioplasty

The procedure entails lengthening the hormonally hypertrophied clitoris by release of the suspensory ligament and resection of the ventral chordee. In order to allow for urination while standing, the natal female urethra is lengthened with the use of labia minora, vaginal musculomucosal flaps, and buccal mucosal grafts. The native urethral plate may be divided to elongate the neophallus; however, this division necessitates additional urethroplasty to recreate a functional neourethra (Stojanovic and Djordjevic, 2015; Djordjevic and Bizic, 2013). Alternatively, the urethral plate may be left intact by using a W incision anterior to and above the urethra (Hage, 1996). Local flaps for urethral reconstruction include dorsal clitoral flaps, which incorporate a superior buttonhole to allow passage of the flap over the neophallus, and inferior labia minora flaps (Stojanovic and Djordjevic, 2015; Hage, 1996). Reconstruction of the bulbar urethra can be bolstered or extended by an anterior vaginal wall flap (Stojanovic and Djordjevic, 2015; Djordjevic and Bizic, 2013). On completion of the urethroplasty, the clitoral bulbs around the neourethra are closed (Stojanovic and Djordjevic, 2015).

Additional masculinization of the lower abdominal and pubic areas may be performed with mons resection. This procedure, performed through a Pfannenstiel incision, is designed to resect and reposition excess fatty tissue often found overlying the natal female pubis. Anchoring of Scarpa fascia to the rectus sheath aids with stabilization of the pubic tissue. The mons resection is typically performed during placement of the testicular prostheses, so as not to communicate with the suprapubic tube, placed at the time of the initial metoidioplasty surgery. The mons resection helps to create the illusion of a longer phallus following metoidioplasty.

Although metoidioplasty may permit urination while standing, it does not allow placement of an erectile device, and it is unlikely that individuals undergoing metoidioplasty will be able to engage in penetrative intercourse (Perovic and Djordjevic, 2003). In addition, scrotal reconstruction following metoidioplasty positions the scrotum in a lateral, rather than an anterior, position. As such, patients may describe their testicles as being positioned “between their legs” rather than “in front of their legs.” Patients are hospitalized for 2–3 days to allow for pain control, intravenous antibiotics, and incisional care. Urination through the penis typically begins about 3 weeks after the procedure, following assessment of the urethral conduit. The suprapubic catheter is removed once the patient demonstrates effective transurethral voiding. Complications following metoidioplasty include, but are not limited to, hematoma, delayed healing, infection, and urethral fistula and/or stricture.

The metoidioplasty procedure is less complex compared with phalloplasty, avoids the disadvantage of additional scarring at remote donor sites, and may be converted to a phalloplasty at a later date, if desired. For some transmen, these considerations are sufficient to warrant the choice of metoidioplasty over phalloplasty.

As previously mentioned, some individuals who have undergone metoidioplasty request subsequent conversion to a phalloplasty. In such circumstances, the glans penis, representing the former glans clitoris, is de-epithelialized and separated from the reconstructed urethra. In addition, one of the dorsal clitoral nerves is harvested for later coaptation to the medial antebrachial cutaneous nerve of the forearm. The glans-urethral construct is transposed subcutaneously and anchored in position to the pubic symphysis. The now redundant skin of the penile shaft, representing the former skin of the labia minora, is excised. If possible, the scrotum is repositioned with anterior advancement of the previous scrotoplasty. The remainder of the procedure follows the principles of the phalloplasty outlined in the next section.

Phalloplasty

Phalloplasty represents the most complete genitoperineal transformation for transmen. Phalloplasty techniques may be divided into pedicled flaps and free flaps. Pedicle flaps transfer tissue, typically from the thigh, groin, or lower abdomen to reconstruct the penis, whereas free flaps involve the microsurgical transfer of tissue from a remote location.

The suprapubic phalloplasty is a pedicled flap technique and gives reasonable results (Bettocchi et al., 2005). A flap is raised on the anterior abdominal wall and rolled into a tube, which becomes the penis. A combination of vaginal epithelium and skin can then be used to create a neourethra, although this tube is seldom of sufficient length to open at the tip of the new phallus and typically opens ventrally. Nevertheless, it does allow micturition in the standing position. The clitoris is left in position at the

base of the new phallus to provide sexual sensation. If erectile function is required, and tissue is sensate, an inflatable prosthesis can subsequently be used.

Abdominal phalloplasties have largely been replaced in modern clinical practice by free-flap techniques. The radial forearm free flap remains the gold standard for phallic reconstruction. This procedure transfers a full thickness flap, including the radial artery, venae comitantes, cephalic vein, and lateral and medial antebrachial cutaneous nerves, from the forearm to reconstruct the penis and urethra. The perineal reconstruction is performed with construction of the fixed, or membranous, urethra, from the vaginal and vestibular lining, as well as scrotal reconstruction with labia majora flaps. Urethral complications, including both strictures and fistulae, are not uncommon, and additional, secondary procedures performed at a later date are required for placement of testicular implants and the erectile prosthesis. Usually, phalloplasty is performed with two surgical teams. One team performs the vaginectomy, colpocleisis, creation of the membranous urethra, scrotoplasty, and placement of a suprapubic tube, while the second team harvests and shapes the forearm flap, then closes the forearm donor site. The forearm flap is divided into two parts; a “tube within-a-tube” technique is used to create the neophallus. The urethra is created from tubularization of the ulnar border of the flap, and the skin of the penile shaft is created from the skin of the radial border of the flap. After detachment from the donor site, the neophallus is put into position on the pubic symphysis; the urethral anastomosis is performed first and then the blood vessels are anastomosed. Nerve wraps are placed over the neurotomy. Placement of penrose drains in each groin and layered closure of the skin complete the procedure.

Closure of the forearm donor site is performed by reapproximation of the muscle bellies over a closed suction drain. A skin graft may be applied to the forearm donor site, or, alternatively, a bilayer wound matrix may be placed. If a wound matrix is used, a skin graft is performed at a later date. Most often, negative-pressure wound therapy (NPWT) in conjunction with a topical antimicrobial dressing is used to dress the forearm donor site. A light compression wrap is then applied. Postoperatively, patients are maintained on a variable duration of bed rest with both transurethral and suprapubic catheters. The phallus is maintained in a vertical position with a soft gauze dressing. Urination through the penile urethra may begin as early as 3 weeks following phalloplasty.

Perhaps the next most used technique for phalloplasty is the use of tissue from the thigh, known as the anterolateral thigh (ALT) flap. Similar to the forearm technique, tissue, including the lateral femoral cutaneous nerve, may be transferred from the thigh to construct the penis. A musculocutaneous latissimus dorsi (MLD) flap may also be used for phalloplasty. Two downsides of this flap are the lack of a sensory nerve in the donor tissue and potential bulk of the constructed phallus.

Testicular implants and penile prostheses can be placed at a secondary procedure. Although the testicular implants may be placed as early as 3 months following phalloplasty, the penile prosthesis is typically placed 9 to 12 months after the phalloplasty. This amount of time allows the development of protective sensation, which is important for retention of the erectile device. Anchoring of the prosthesis can be a challenge and often requires fixation to the pubic bone. Anchoring of the prosthesis may be performed with suture fixation to the periosteum of the pubis, or, alternatively, bone anchoring. In addition, the prostheses can be wrapped with an acellular dermal matrix to help form a “pseudo corpora cavernosa.”

Complications

Unfortunately, phalloplasty in FtM surgery carries a high complication rate (overall >40%) (Monstrey et al., 2009). Complications following phalloplasty can be divided into early and late categories. Early complications tend to be flap-related and include delayed wound healing and flap failure. Additional early complications include venous thromboembolism, bleeding, and infection.

Most late complications are urologic in nature. Other late complications can be related to the erectile prosthesis; these include erosion, either through the shaft skin or urethra, dislodgement, and mechanical failure. Furthermore, disruption of the neurotomy can occur during placement of the prosthesis, resulting in loss of sensation to the phallus.

Urethral problems occur commonly after phalloplasty (Hoebeker et al., 2005), and additional procedures may be required. Complications include urinary tract infection, urethrocutaneous fistula, urethral stricture, urethral diverticula, and hair within the reconstructed urethra. Symptoms may include a weak urinary stream, leakage of urine from the penile shaft or scrotum, dysuria, urinary frequency, incomplete emptying, and inability to urinate (Hoebeker et al., 2005).

Conclusion

The vast majority of existing information on outcomes in female-to-male genital reconstruction is considered low-quality evidence (Sutcliffe et al., 2009). Existing studies on patient satisfaction are limited by a general lack of validated, standardized methods, a paucity of controlled studies, little prospective data collection, and poor response rates in long-term follow-up studies.

Gender reassignment surgery is one of the most challenging surgical disciplines. In FtM surgery, the gold standard technique has not yet been identified and, depending on a patient's request, a different surgical approach should be used. Furthermore, very few centers have the experience of, and subsequently can offer, different techniques for FtM gender reassignment. Moreover, complications are frequent and limitations to the ideal reconstruction are present with every technique used. The complex psychological background of the patients and their expectations further challenge gender reassignment surgeons. Thus, a very skilled, dedicated and cooperative team is necessary to achieve good results.

MENTAL HEALTH, ETHICS AND THE LAW

Psychological Aspects of Male Reproductive Medicine

Amanda Kohlmeier and Susan Klock, Northwestern University Feinberg School of Medicine, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Infertility, the inability of a couple to achieve pregnancy after 12 months of unprotected intercourse with regular, ovulatory cycles, affects approximately 1 in 10 couples of reproductive age. Of those, approximately 30%–40% of the cases are attributed to male factor infertility. Even though male factor infertility contributes to a significant percentage of infertility cases, the research on the psychological aspects of male infertility is disproportionately low. The purpose of this article is to provide an overview of the psychological aspects of male reproductive medicine and male infertility and its treatment.

The infertility journey begins after a couple has been trying unsuccessfully to conceive for many months and then see their physician to begin a fertility work up. The female partner typically has a physical exam, blood tests to check her hormone levels and other diagnostic tests to determine her fertility status. The male partner will also undergo blood tests and a semen analysis to determine if there is a male factor involved. The semen analysis can yield several results in relation to volume, total sperm count, sperm concentration, motility and morphology. **Table 1** provides information with reference ranges for normal semen analysis results (Cooper et al., 2010).

When abnormal results are found on the semen analysis they can occur in one or several aspects of the semen parameters. Some common male factor diagnoses are:

- (1) Azoospermia: complete absence of sperm from the ejaculate, present in about 1% of all men and 10%–15% of infertile men.
- (2) Aspermia: complete absence of seminal fluid emission upon ejaculation.
- (3) Oligospermia: low sperm count, defined by the World Health Organization (WHO) as concentrations less than 15 million sperm/mL, which is consistent with the 5th percentile for fertile men. Oligospermia is further classified as:
 - (a) Mild: concentrations 10–15million sperm/mL;
 - (b) Moderate: concentrations of 5–10 million sperm/mL and;
 - (c) Severe: less than 5 million sperm/mL.

Differentiation of azoospermia from severe oligospermia is accomplished by examination of the pellet of a centrifuged semen sample on at least two occasions.

- (4) Teratozoospermia, also known as teratospermia, is a semen alteration in which there is a large number of spermatozoa with abnormal morphology.

There can be many causes of male factor infertility but most causes are unknown. Common causes of male infertility include genetics, infection, trauma, varicocele, meningitis, diabetes, fever, alcohol or drug abuse, exposure to chemotherapy, and/or radiation, pharmaceuticals that interact with testosterone. Some causes may be reversible, others are not but can be overcome with treatment, such as in vitro fertilization (IVF) with intracytoplasmic sperm injection (ICSI).

Psychological Research on Male Infertility

Despite the cause, the psychological impact of male infertility is significant. Emotional distress, such as depression, anxiety or sexual dysfunction are commonly reported after a diagnosis of male factor infertility. In addition, sexual performance anxiety can develop and further affect a man's psychological state. Even though male factor infertility contributes to a significant percentage of infertile

Table 1 Normative semen parameters (Cooper et al., 2010)

Volume	1.5 mL (1.4–1.7)
Total sperm count (count × volume)	39 million per ejaculate (33–46)
Sperm concentration (number per milliliter)	15 million/mL (12–16)
Vitality (live spermatozoa)	58% live (55–63)
Progressive motility (forward movement)	32% (31–3)
Total motility	40% (38–42)
Morphology (normal shape)	4% (3%–4%)

One-sided lower reference limits, the 5th centiles (95th percent confidence intervals).

cases, the research on the psychological aspects of infertility are disproportionately focused on women. [Petok \(2006\)](#) provides a thorough overview of the psychological reaction to male infertility including theoretical perspectives and cultural perspectives.

In terms of the research on the psychological impact of male infertility, [Luk and Loke \(2015\)](#) conducted a systematic review of the literature on the impact of infertility on psychological well-being. In their review they identified three studies that specifically focused on men's adjustment to infertility. One study by [Ahmadi et al. \(2011\)](#) assessed symptoms of depression in a sample of 114 infertile men in Iran. Ahmadi et al. noted that in traditional cultures, fatherhood is regarded as the equivalent of manhood. Therefore, there can be a stigma against infertile men as being "futile and useless" and their masculinity is "questionable." In order to assess the psychological impact of infertility among men, the authors assessed demographic information and depression in a series of men presenting to an infertility center. Using the Beck Depression Inventory, they found that 43% of the sample had depressive symptoms consistent with severe depression. Having less education (lower than a 12th grade education) was associated with greater depressive symptomatology. These rates are comparatively high compared to the 15% reported by [Drosdzol and Skrzypulec \(2009\)](#) and 5% reported by [Volgsten et al. \(2008\)](#) in European samples. [Gao et al. \(2013\)](#) found that in a sample of 1468 Chinese infertile men, 38% endorsed symptoms of anxiety and 15% reported symptoms of depression. Moreover, 19% of infertile men reported experiencing premature ejaculation and 18% suffered from erectile dysfunction. [Mikkelsen et al. \(2013\)](#) reported 28% of their sample of 210 Danish men with infertility reported that reduced sperm quality affected their perceptions of their masculinity and adversely affected their sense of well-being. In contrast to these findings, [Holter et al. \(2007\)](#) found no difference in psychological adjustment between men with male factor infertility compared to men with other causes of infertility prior to beginning IVF or ICSI treatment.

[Williams and Zappert \(2006\)](#) noted that grief reactions are common after a diagnosis of infertility. As [Mahlstedt \(1985\)](#), in her classic article describing the psychological aspects of infertility, described the psychological adjustment can be conceptualized through a loss and grief framework. The losses identified with male factor infertility include: (1) loss of relationship(s) with spouse, fertile friends, family members; (2) loss of health; (3) loss of sexual satisfaction; (4) loss of status in social community and; (5) loss of self-esteem. These losses are frequently expressed during counseling with men after the diagnosis of a male factor infertility.

Clinical Description—Grief and Loss

Infertile men frequently discuss feeling fearful that their infertility will undermine their relationship with their wife or significant other because it will prevent their partner from fulfilling their important life goal of having a child. Additionally, this loss is sometimes expressed as giving the partner permission to leave the relationship in order to pursue a relationship with a fertile man. Other losses related to relationships are the changes in relationships with fertile family or friends. Men often feel reluctant to talk to their male friends about their infertility diagnosis due to the association of infertility with virility and masculinity. Men may also remove themselves from family gatherings and interactions where the topic of having children will come up because they do not want to have to disclose or explain their infertility situation to others. Particularly in our pro-natal culture, "when are you going to have a baby?" is a common question for couples soon after they get married or begin living together. This common, seemingly benign, question can prompt anxiety, withdraw and frustration to a man with infertility.

Another loss associated with male factor infertility is loss of health. Men are frequently required to undergo several blood tests, semen analyses and possible other procedures, such as testicular biopsies, in the course of the diagnosis and treatment of infertility. The frequent trips to the clinic, the procedures themselves and the medical interventions to create a pregnancy can all contribute to the medicalization of reproduction and the perception of being "sick" in otherwise healthy men.

A loss that has received significant attention has been the loss of sexual satisfaction and sexual self-esteem. Several researchers have documented the occurrence of erectile dysfunction, diminished sexual interest and activity following a diagnosis of male factor infertility ([Luk and Loke, 2015](#)). Some men describe feeling like "what is the point?" of having sexual intercourse after their diagnosis because the reproductive aim of intercourse has been negated. For men with oligospermia, timed intercourse can increase performance demand and anticipatory anxiety which detracts from actual performance, thus creating a cycle of pressure to perform at a specific time, anticipatory anxiety and subsequent sexual difficulties. Additionally, assisted reproductive treatments often require the man to produce a semen sample at home or in the clinic to use for intrauterine insemination or IVF. The timed, clinical, nature of producing these samples as well as the pressure to produce a "good" sample are all contributors to the concerns about sexual functioning.

The other losses, such as the loss of self-esteem and the perceived loss of status in one's social community have received less attention in the literature on the psychological aspects of male infertility but are evident in clinical interactions with male infertility patients. One study, by [Nachtigall and his colleagues](#) reported that fertility is central to a man's sense of gender identity and that infertility may pose a threat to masculinity ([Nachtigall et al., 1992](#)). These authors found that almost two thirds of infertile men that they interviewed reported being preoccupied with their loss of physical potency and felt stigmatized related to their loss of masculinity that infertility caused. Additionally, as men consider various pathways to parenthood (IVF/ICSI, donor sperm use, adoption) or child-free living, they frequently consider these options in the context of their social community. "What would people think? is a common starting question related to status within their social community as men consider sharing their infertility situation with others or begin talking with others about child-free living, adoption or donor sperm use. The perceived loss of status men experience as they consider not having children is significant. Men frequently discuss feeling like they will not be as

respected or considered independent until they have children of their own. Nongenetic options for parenting (adoption, donor sperm use) frequently lead to concerns of not being the “real” father of a child and perceived loss of status as a father to a non-genetically related child.

Psychological Factors Influencing Male Fertility

In recent years, psychological stress has been postulated to affect male infertility by affecting testosterone levels and subsequent spermatogenesis. Nargund (2015) provides a review of this topic and possible mechanisms of action for both acute and chronic stress. Stress could affect fertility via the hypothalamic–pituitary–gonadal axis. Clinical studies investigating the interaction of stress and infertility have yielded conflicting results. Some studies have shown reduced sperm concentration and changes in other semen parameters during times of stress (exams, war, work stress). Other studies do not find this effect. Additionally, behaviors used to cope with stress (smoking, drinking alcohol, using drugs) can also affect semen parameters. Li et al. (2011) conducted a review of socio-psycho-behavioral factors and semen quality. In their review of 57 studies, they investigated several factors that were hypothesized to affect semen quality. These included: age, body mass index (BMI) psychological stress, smoking, alcohol and caffeine consumption, passive smoking, and sedentary lifestyle. Based on the results of their review, they concluded that age is negatively associated with semen volume. They also concluded that psychological stress could reduce sperm density and progressive motility and increase the number of abnormal sperm. Specifically, they found that job stress, life events or social support related stress could adversely affect semen quality. Smoking was found to be a risk factor for all semen parameters. Alcohol consumption was associated with lower semen volume. The effect of BMI and caffeine consumption was considered uncertain on the five most common sperm parameters. It should be noted that the studies reviewed by Li et al. included samples of fertile and infertile men, and varied in sample size and semen parameters assessed. The largest number of studies addressed the impact of smoking on semen and indicated a clear impact. Smoking is clearly a public health problem and is a behaviorally modifiable variable which can affect male fertility.

Male Psychological Response to Treatment (IVF)

After a diagnosis of male infertility, the couple may consider treatment options to address the infertility problem in order to achieve a pregnancy. One of the most common treatments for male factor infertility is IVF with or without ICSI. The psychological aspects of IVF have been studied extensively (see Verhaak et al., 2007 for a review) but these studies have predominantly focused on women. An exception to this is a recent review by Martins et al. (2016) who examined studies on men’s adjustment to infertility treatment to determine if male psychological adjustment to unsuccessful infertility treatment varies over time and if there are any psychological protective or risk factors that are related to psychological maladaptation. Martins et al. identified 12 studies that met their criteria of quantitative, longitudinal design and measurement of psychological adjustment. The study time frames varied from 4 weeks to 5 years post treatment.

In three studies looking at men’s adjustment after unsuccessful treatment, Martins et al. found that men reported an increase in depressive symptoms within a few weeks after the baseline assessment. Two studies measured anxiety in men after a diagnosis of azoospermia. In general, they found lowered levels of anxiety from baseline to 4 weeks after diagnosis. In terms of coping strategies, it was found that the use of active coping strategies decreased and the use of religiousness and seeking meaning coping increased in men 4 months after the infertility work-up. In terms of social support, men reported less social support and more negative reactions and comments from family and friends 1 year after beginning infertility treatment.

Psychological Support and Counseling During Male Infertility Treatment

After a diagnosis of male infertility, the couple is confronted with a decision about whether to pursue medically assisted reproduction (MAR) (IVF, ICSI, donor sperm use). Urologists or fertility specialists frequently refer their patients to a mental health professional with expertise in infertility counseling. The initial counseling can be focused on helping process the emotional reaction to the infertility diagnosis and discussing the decision whether to pursue MAR. Wischmann (2013) sites clinical research with recommendations for increasing the utilization of counseling by infertile men. These recommendations include:

- (1) Provide pre-treatment educational brochures about men, for men
- (2) Explain the potential benefits of counseling to both partners
- (3) Introduce psychological counseling and support before treatment begins
- (4) Make direct contact and connection with male patients
- (5) Present counseling and psychological support as an integrated part of infertility treatment

These suggestions can ease the burden for male patients and facilitate the delivery of psychological care. Given the concern about depression, anxiety or sexual dysfunction, the use of a psychological screening tool, such as the FertiQol (Boivin et al., 2011) or the SCREENIVF (Verhaak et al., 2010) can be used to identify men who may benefit from a psychology counseling referral.

If the couple decides to pursue IVF, with or without ICSI, it is helpful to have one or more counseling sessions to discuss the treatment process, including the steps in the treatment (injectable fertility medications, ultrasound monitoring and blood tests, oocyte retrieval, embryo creation and transfer, waiting for pregnancy test results). This helps the male patient increase his treatment knowledge and subsequently provide more focused support for his partner during treatment. During pre-treatment counseling the male partner can also express his feelings of sadness, loss, and guilt and those feelings can be processed and discussed with his partner. Then counseling can progress to a discussion of coping during IVF and ways the man can use instrumental coping skills to be engaged in the treatment process and support his partner during the treatment. Developing a treatment calendar, helping administer the medication injections, checking in via texts or phone calls and setting aside time for the couple to discuss their thoughts and feelings about treatment can all be adaptive coping strategies to use during IVF. The mental health professional can model and role play ways in which the partner can be supportive and help manage the treatment stress.

In the case of azoospermia, where the only option to create a pregnancy is donor sperm use, the role of psychological counseling and support is also important. In this context, the patient and his partner are typically seen for one or more sessions of counseling to prepare them for this unique family building options. [Klock and Maier \(1991\)](#) have previously described the topics to be covered during these types of consultations. The consultations begin with the mental health professional helping the man process his feelings about the diagnosis and its cause. His wife or partner can also express her sadness, frustration and support for her partner as they reconsider the joint goal of parenting. If they decide against child-free living, then the mental health professional can review the various types of family building options, including donor sperm use, adoption or foster parenting. The advantages and disadvantages of each family building option can be discussed.

If the decision is made to pursue donor sperm use, then specific psychological and social issues need to be considered before beginning with treatment. First, the man must examine his thoughts and beliefs about fatherhood. This usually begins with a recollection of his own relationship with his father, its strengths and weaknesses, and the patient's perception of the importance of genetic versus relationship bonds with his father. The next topic is typically the man's perception of the importance of the genetic connection or the relationship connection in the development of a paternal relationship with a child (nature vs. nurture). Men who feel that the preponderance of the father-child relationship is predetermined by the genetic relationship may have a more difficult time accepting donor sperm use and often opt not to undergo this treatment. If the genetic connection is extremely important to the patient, then the use of a related (brother, cousin) sperm donor may be discussed. The medical and psychological screening of known gamete donors is provided by the American Society for Reproductive Medicine (ASRM) practice committee ([ASRM, 2013](#)). If a known donor is not possible or preferred, then an anonymous donor can be selected from a sperm bank. The selection of a donor is another topic for pre-treatment counseling. Typically, the couple selects a donor that has physical resemblance to the patient in terms of ethnic background, height, hair color, eye color, and other characteristics. In addition, sometimes the patient selects a donor that physically resembles him by using a photo matching process. Alternatively, some patients do not want to see photos or other additional materials provided by the donor because they feel it interferes with their ability to bond with the potential child.

An important topic in the donor sperm counseling is the discussion of privacy and disclosure. This refers to the discussion with the prospective parents about their plans to tell the child, family and friends about the child's donor sperm origin. The discussion of these two topics is interrelated because the plan to tell the child is often closely related to plans to tell others. Couples may tell family and friends about the infertility diagnosis and therefore feel they "have to" tell about the use of donor sperm once the wife or partner becomes pregnant. The decision to tell others directly relates to whether they tell the child. A follow-up study of donor sperm parents found that most parents regretted telling other people because they felt that they had to tell the child for fear of the child finding out from someone other than the parents ([Klock et al., 1994](#)). An additional concern about telling others is that parents worry that their child may be angry or hurt if he/she found out that others knew of their conception story before they did. While most couples intend to tell their child about their donor conception origin, counseling by a mental health professional can provide a neutral place to discuss the decision and to practice how to tell the child. Parents often feel that they "don't have the words" to use to describe this unique form of family building to a pre-schooler or young child. Related to the disclosure discussion is the decision of whether or not to use an identity release donor. An identity release donor is a donor who agrees to provide identity related information to the donor conceived child when the child reaches the age of 18. This is an increasingly common occurrence in the field of donor sperm use and has led to the development of many half-sibling family groups.

For all of these psychological support and counseling services, provision of service by a mental health professional with expertise in infertility is a must. The detailed, specific fund of knowledge about infertility and its psychological concomitants is needed in order to provide optimal psychological services. Guidelines for the qualifications of mental health professionals are provided in [Mental Health Professional Group of the American Society for Reproductive Medicine \(2006\)](#). In addition, support information for patients about donor sperm use can be found at [RESOLVE.org](#) (a patient advocacy website), [ASRM.org](#) and [BICA.org](#) (British Infertility Counseling Association).

Conclusion

In conclusion, male infertility affects a significant proportion of couples wishing to become pregnant. While historically the focus on the psychological aspects of infertility has been focused predominantly on women, in the past several years more emphasis has been placed on understanding the man's experience and to increase the provision of support to infertile men as they pursue their

family building goals. While men may process and cope with the diagnosis of infertility differently than women, their experiences deserve equal attention, sensitivity and focus in the clinical and research realms.

Legal and Ethical Aspects of Male Reproduction

Lawrence S Ross, University of Illinois at Chicago, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

In the past fifty years there have been significant advances in the science and technology of male reproductive medicine and surgery. These advances, coupled with the rapidly expanding development of advanced reproductive technologies, and changes in societal attitudes toward same sex relationships and issues of gender identification, have created legal and ethical challenges for those who wish to parent children. This chapter explores these topics and attempts to educate the reader on the present status of these problems with emphasis on the male.

Sperm Donation, Storage, and Use

Artificial insemination for reproduction in humans was first performed in 1790. It remained the sole method of reproductive technology until the early 1950s when in-vitro fertilization (IVF) was successful in animals. Bavister B.D., (2002) Early history of in vitro fertilization. *Reproduction* Aug;124 (2):181–96. (Bavister, 2002) The first human birth resulting from IVF using fresh ejaculated sperm was reported in 1978. Steptoe P.C., Edwards R.G., (1978) Birth after the reimplantation of a human embryo. *Lancet*, 1978; 12;2:366 (Steptoe and Edwards, 1978).

Key to the development of IVF as an option for male reproductive disorders, including severe oligospermia and azoospermia, was the ability to successfully freeze and thaw sperm. Although this concept was envisioned in the late 18th century, the first human pregnancy using inseminated frozen/thawed sperm occurred in 1953 and the first live birth was reported in 1963. Banking of cryopreserved sperm from anonymous donors for use by couples in which no sperm can be obtained from the male partner, began in the 1970s. Since that time the use of donor sperm, where autologous sperm is not available, has expanded to gay single women and men, and all LGBT people wishing to have children. Women desiring pregnancy and child bearing using sperm cryopreserved from a deceased partner add to the complexity of male reproductive treatment options.

The U.S. Food and Drug Administration regulates reproductive tissue (sperm and eggs) intended for donation. People intending to use donor sperm should be advised to use sperm only from banks that have registered with and follow FDA guidelines. This information can be accessed on line. CFR - Code of Federal Regulations Title 21 - FDA (Cfr N.d.).

Legal Aspects of Sperm Donation

There are multiple complex issues surrounding sperm donation and very little law addressing these issues. What laws exist are on a state by state basis. In most states with sperm donor laws, the donor has no rights, obligations, or interest with the child born resulting from assisted reproductive technology (ART), which includes artificial insemination or IVF; and the child born as result of ART has no rights, obligations, or interest with the sperm donor. In the case of artificial insemination these legal protections may only exist if the insemination is done by a licensed medical professional. Self-insemination with a donor's sperm may not protect the donor, woman, couple, or child from issues of paternity, child support, or visitation rights. In some states, if a child is born resulting from use of donor sperm, the husband may not be recognized by the state as the father. Similar issues can occur with egg or embryo donation and surrogacy births. 'Ross & Zuckerman, LLP' <http://www.infertilityattorney.com/articles.html> (Infertilityattorney, N.d.). The Uniform Parentage Act of 2002 is an attempt to deal with these issues. 'Uniform Parentage Act' www.uniformlaws.org/shared/docs/parentage/2016AM_AmendedParentage_Draft.pdf (Uniformlaws, N.d.).

A more complex and controversial issue is posthumous reproduction using sperm cryopreserved after death. Land S., Ross L.S., (2002) Posthumous reproduction: current and future status. *Urologic Clinics of North America*; 29 (4), 863–871 (Land and Ross, 2002) Post-mortem reproduction occurs in nature. The female praying mantis kills her mate during copulation. In humans the concept of producing offspring using sperm after the death of a man is a subject of both legal and ethical debate. In addition, there are numerous technical issues regarding the extraction of sperm: how long is the sperm viable after death; should the sperm be extracted from the vas deferens, epididymis, or testis? Various reports have shown that sperm are still functional for intervals of 24–30 h after death. In theory, ejaculated sperm could be obtained from a patient deemed brain dead but kept on life support for the harvest of other organs, but such retrieval has rarely been reported.

The prevalence of and actual use of post-mortem sperm for procreation are anecdotal. The true number of offspring conceived with post-mortem sperm is unknown. The legal issues surrounding posthumous reproduction are similar to those affecting other "organ" donations, but can be infinitely more complex. Patel Z.P., Ross H.E., Ross L.S., (2012) Request for posthumous fatherhood with perimortem surgical sperm retrieval. *Assisted Reproduction Techniques: Challenges and Management Options*; 353 (Patel et al., 2012).

Most guidance is determined state by state. The Illinois Uniform Anatomical Gift Act states: "Any individual who is of sound mind and has reached the age of 18 may give all or any part of his or her body as an anatomical gift. Such a gift, of course, would take effect only upon the individual's death. Making such a gift in advance eliminates the need to obtain consent from anyone else.

If an individual has not provided for an anatomical gift before death, another person, as listed in the priority below, may make an anatomical gift on behalf of the decedent (regardless of age), after or immediately before death:

1. The decedent's spouse.
2. The decedent's adult sons or daughters.
3. Either of the decedent's parents.
4. Any of the decedent's adult brothers or sisters.
5. The guardian of the decedent at the time of his/her death.
6. Any person authorized or under obligation to dispose of the body."

Of interest, sperm is rarely referenced in such state guides, or is specifically excluded. Illinois Anatomical Gift Act (755 ILCS 50/) <http://www.ilga.gov/legislation/ilcs/ilcs5.asp?ActID=2114&ChapterID=60>(lga, N.d.)

The number of potential legal issues associated with donor sperm are considerable. They include suits that have been filed for mistaken labeling of specimens involving race or ethnicity of the donor, undisclosed familial genetic issues, failure of laboratory systems to protect cryopreservation leading to lost sperm samples, and transmission of HIV or other infections. Among the most interesting was a case in which the wife of a prominent and wealthy man secretly banked a specimen of her husband's sperm. She informed the laboratory personnel that her husband was too busy to come to the lab and she would bring in the specimen with a signed and notarized contract from her spouse. Her plan was to have the husband murdered, become pregnant with his sperm, and lay claim to his considerable estate. The plan was foiled when the lab called the husband because the second year's storage fee was not paid. The wife offered an undercover police officer \$5000 to carry out the murder, was arrested, convicted at trial, and sentenced to 30 years in prison. *The Heir, His wife, and the Hit Man*, by Nancy Millman, *Chicago Magazine* 1999;48:57–9, 116–9. See, <http://www.chicagomag.com/Chicago-Magazine/1982-2000-1982/February-1999-Table-of-Contents/> (Chicago, 1999). Most semen laboratories today require donors to appear in person with valid ID, and produce the specimen on site.

Ethical Aspects of Sperm Donation

The use of donated sperm raises a number of ethical issues. With regard to use for reproduction these include, but are not limited to: 1) rights of the donor; 2) rights of clients (purchasers of sperm); 3) criteria for selection of donors; 4) amount of sperm a single man can donate; 5) costs associated with use of donor sperm.

The rights of donors include the right of anonymity and protection from claims of parenthood or financial obligations from offspring or parents. Clients purchasing sperm from commercial sperm banks have the right to expect that donors have had screening for potential transmission of communicable genetic abnormalities, sexually transmitted diseases including HIV, gonorrhea, syphilis, HPV, CMV, and most recently, Zika virus. Testing for or family history of potentially adverse genetic disorders are a frequent concern for recipients of donor sperm. Most sperm banks have arbitrary selection criteria for age range, height, and education. Virtually all commercial banks include race, ethnic origin, and religion of donors. One bank, the Repository for Germinal Choice which existed in California from 1980 to 1999 was known as the "Nobel prize sperm bank", although only one Nobel prize winner, William Shockley, donated sperm. 'The "Genius Babies" and How They Grew'. See, www.slate.com/articles/life/seed/2001/02/the_genius_babies_and_how_they_grew.html (Slate, N.d.).

Most selection criteria are chosen to attempt to provide recipients with some assurance that they and their potential offspring will be protected from transmissible diseases, and be able to choose desired physical, religious, ethnic, educational, and racial characteristics. Some ethicists raise concerns regarding the phenomenon of promoting "designer" offspring as well as the specter of eugenics. Concerns of the number of specimens a donor can provide and the number of recipients for sperm raise issues of consanguinity. There is little to no regulation for the number of specimens a man may donate. The number of children a single donor has or may have fathered is subject to speculation and there are no reliable statistics available.

'Delivery Man': 9 Sperm-Donation Questions You're Too Embarrassed to Ask'. See, <http://healthland.time.com/2013/11/22/delivery-man-the-9-sperm-donation-questions-youre-too-embarrassed-to-ask>(Healthland, N.d.).

The costs associated with donor reproduction also raise ethical questions. Are sperm and egg donors providing their gametes for reasons of altruism or profit? Could such motives affect or compromise the honesty of donors in the selection process? Donor insemination costs may range from \$300 to \$4000 depending on source of the sperm with lower cost using the male partner's sperm compared to anonymous donor sperm. Typical costs for egg donation can range from \$12,000 to \$20,000 and having a child by surrogacy can be considerably more.

'American Pregnancy Association, Donor Insemination'. See, <http://americanpregnancy.org/infertility/donor-insemination/> (Americanpregnancy, N.d.). 'ConceiveAbilities, Surrogate Mother Pay'. See, <https://www.conceiveabilities.com/surrogates/surrogate-mother-pay>(Conceiveabilities, N.d.).

Other special areas of ethical concern for sperm donation have developed in recent years. These require physicians caring for certain groups of patients to think about future reproductive needs when working with these patients. Medical oncologists must understand and think about the therapies they prescribe and their potential effects on reproductive tissues. Adults who need chemotherapy, radiation, or surgery should be educated and advised to consider preservation of their gametes when possible.

Cryopreservation of sperm can be accomplished quickly and rarely delays oncologic therapy. Egg freezing has advanced in recent years but the process is invasive and requires planning. It must be offered early in the oncology diagnostic workup.

Transgender people contemplating hormonal therapy and/or surgical reassignment should be counseled about their potential desire to parent children as should gay men with conditions that may affect their reproductive potential, including varicoceles. Since varicoceles are found in up to 50% of men with abnormal semen parameters they should be told that there is rarely a significant health concern requiring surgery but it is a common cause of decline in fertility. Recently, the author saw a 20 year old gay male with a large varicocele who wanted to know if he needed surgery. When told the only strong indication would be decline in sperm concentration and motility which can lead to infertility, he said "you know I'm gay". He was asked if he ever thought about the possibility of having a child as a single parent or with a partner and wanting such a child with his genetic material. He was pleased to be alerted to thinking about the issue.

The explosion of marketing for testosterone supplementation for low testosterone ("low T") in aging men has raised ethical concerns in the medical establishment and in government. Data from insurance carriers has shown a steady 10 year rise in prescriptions for supplemental testosterone preparations. Experience with testosterone abuse in athletes brought attention to the deleterious effects of testosterone supplements on male fertility and other research has been suggestive of additional risks including cardiovascular problems and concern in patients with prostate cancer. Because testosterone supplementation has been available to some men without adequate medical consultation or education as to risks (trainers, workout facilities, "Low T" clinics without physicians trained in the proper indications and risks of such therapy) increasing numbers of men of reproductive age have been compromised by such treatment. The magnitude of the problem has recently been examined by the Centers for Disease Control and Prevention (CDC) and a consortium of reproductive urologists. Rao PK, Boulet SL, Mehta A, Hotaling J, Eisenberg ML, Honig SC, et al. (2017) Trends in testosterone replacement therapy use from 2003 to 2013 among reproductive-age men in the United States. *The Journal of Urology* 197 (4), 1121–1126 (Rao et al., 2017).

Recent research has demonstrated the successful development of sperm and oocytes from mouse embryonic and induced pluripotent stem cells. Some progress has been made in the differentiation of human germ cells from human embryonic stem cells and pluripotent stem cells. Given the direction of such research it is theoretically possible to envision the creation of human embryos in the laboratory. Such embryos could be used for research or ultimately for reproductive purposes. The ethical concerns of such developments are being considered internationally. Ishii, T, Reijo Pera, R.A., Greely, T.E. (2013) Ethical and legal issues arising in research on inducing human germ cells from pluripotent stem cell. *Cell Stem Cell*. Aug.; 2 (1): 145–8. See, <http://www.sciencedirect.com/science/article/pii/S1934590913003135> (Sciencedirect, N.d.; Ishii et al., 2013).

MALE REPRODUCTIVE CANCER AND DISEASE

Benign Prostatic Hyperplasia (BPH)

Ervin Kocjancic, University of Illinois Hospital and Health Science System, Chicago, IL, United States

Valerio Iacovelli, University of Rome Tor Vergata, Rome, Italy

© 2018 Elsevier Inc. All rights reserved.

Introduction

Benign prostatic hyperplasia (BPH), is one of the causes of the lower urinary tract symptoms (LUTS) and a common diagnosis among the aging male population with increasing prevalence. The understanding of the LUTS as a functional unit, and the multifactorial etiology of associated symptoms, means that LUTS now constitute the main focus, rather than the former emphasis on BPH ([European Association of Urology, 2016](#); [Gratzke et al., 2015](#); [McVary et al., 2011](#)). LUTS present with dysfunction of both storage and emptying phase as well as the post micturition signs. These symptoms are nonspecific in their presentation and multifactorial in origin. LUTS are a progressive and age related but not sex- or organ-specific. They cause bother and impair quality of life ([Agarwal et al., 2014](#)).

Traditionally, LUTS have been related to bladder outlet obstruction (BOO) as a result of benign prostatic obstruction (BPO), which is often caused by benign prostatic enlargement (BPE) resulting from the histologic condition benign prostatic hyperplasia (BPH) ([Abrams et al., 2002](#)). Several recent studies have shown, however, that LUTS are not necessarily related to prostatic size. Major attention is currently oriented to the bladder wall; bladder dysfunctions, such as detrusor underactivity, detrusor overactivity and other functional abnormalities ([van Koeveeringe et al., 2014](#)).

As the world population ages, the incidence and prevalence of BPH and LUTS have rapidly increased ([Lepor, 2005](#)). Historical studies have examined nonmodifiable risk factors—including age, genetics and geography—that have important roles in the etiology of BPH and BOO ([Parsons, 2010](#)). However, several modifiable risk factors present new opportunities for treatment and prevention ([Chughtai et al., 2016](#)).

Epidemiology

Approximately 50% of men > 50 years of age will have pathological evidence of BPH, with this number increasing to > 80% as men reach their eighth decade of life and older ([Berry et al., 1984](#)).

LUTS are strongly associated with aging and progress dynamically: for some individuals LUTS persist and progress over long time periods, and for others they remit ([Société Internationale d'Urologie \(SIU\), Lower Urinary Tract Symptoms \(LUTS\), 2013](#)).

Several studies have examined the geographical variations in BPH and LUTS prevalence. Men from Southeast Asia have significantly smaller prostate volumes than men from western countries. Although differences in geographical prevalence for prostate disease (including BPH) have been documented, the reasons for such differences are poorly understood. However, these differences could be due to genetic factors and/or environmental differences ([Jin et al., 1999](#)).

Etiology

Many modifiable and nonmodifiable factors can increase the risk of development and progression of BPH and LUTS.

Age

BPH and LUTS increase with age, which has been confirmed by numerous studies ([Berry et al., 1984](#)). Prostate volume increases at a median rate of 0.6 mL per year. Although symptom severity cannot be correlated directly with prostate volume, having a large prostate volume is a risk factor for the development of LUTS. Thus, the incidence of LUTS also increases with age. That is, larger prostates are associated with increased risks of urinary retention, increased future need for surgery and clinical progression of BPH ([Société Internationale d'Urologie \(SIU\), Lower Urinary Tract Symptoms \(LUTS\), 2013](#)).

Metabolic Syndrome

Many studies have investigated associations between metabolic syndrome and BPH-related LUTS (BPH-LUTS) and results of several studies support possible roles for the individual components of the syndrome in the development of BPH-LUTS ([Vignozzi](#)

et al., 2016). Metabolic syndrome includes hypertension, dyslipidaemia, glucose intolerance, central obesity and insulin resistance with compensatory hyperinsulinaemia (De Nunzio et al., 2012).

- *Obesity and BPH–LUTS.* Obesity, and in particular visceral obesity, is often comorbid with BPH (Parsons, 2010; Vignozzi et al., 2016). More importantly, the risk of LUTS progression also increased as a function of obesity (BMI ≥ 35 kg/m²), visceral adiposity (waist circumference > 42 in., 106.7 cm). The influence of obesity on prostate overgrowth was observed also in early adulthood. Overall, these findings support the concept that the treatment of obesity might be important in the prevention and treatment of LUTS (Vignozzi et al., 2016).
- *Glucose intolerance and BPH–LUTS.* A possible association between BPH and glucose intolerance or overt T2DM has also been noted (Hammarsten et al., 1998). In particular, in patients with BPH, a history of T2DM increased the risk of moderate–severe LUTS twofold (Joseph et al., 2003). Interestingly, individuals with insulin resistance who develop compensatory hyperinsulinaemia might directly and/or indirectly affect several molecular signaling pathways that promote prostatic growth and inflammation (Nandeesha et al., 2006).
- *Dyslipidaemia and BPH–LUTS.* Circulating total cholesterol and HDL cholesterol are positively and negatively associated with prostate enlargement, respectively (Nandeesha et al., 2006). Furthermore, it has been shown that men with hypertriglyceridaemia had decreased likelihood of storage LUTS improvement during the follow-up period, and greater abdominal fat mass was associated with storage LUTS progression. In the same study, lower HDL cholesterol levels, as well as lower testosterone and higher oestradiol levels, were associated with worsening of voiding LUTS (Martin et al., 2014).
- *Hypertension and BPH–LUTS.* The role of hypertension is debated. Increased blood pressure seems to be associated with an increased odds ratio for surgical treatment of BPH (Gann et al., 1995).

Although insulin resistance and visceral obesity are considered to be the main pathophysiological aberrations of metabolic syndrome, a number of other factors, such as a proinflammatory state and sex steroid imbalance, could also be involved in its pathogenesis and clinical manifestation. In particular, chronic low-grade inflammation has been recognized as a central pathogenic mechanism underlying the development of individual metabolic syndrome components. In addition, in the past decade, clinical and preclinical evidence has confirmed that chronic inflammation also has a determining role in inducing BPH–LUTS (Fibbi et al., 2010; Vignozzi et al., 2014). That is, an inflammatory insult is the most plausible candidate bridging the mechanistic gap between metabolic syndrome and BPH–LUTS (Fibbi et al., 2010; Vignozzi et al., 2014).

Genetics

To date few genetic studies have focused on BPH. A recent study reported that variants in 2q31 and 5p15 are associated with aggressive (defined by multiple criteria) BPH (Qi et al., 2013). Furthermore, twin studies have suggested that heritability is an important determinant of disease severity in BPH, including the development of LUTS.

Pathogenesis

The pathophysiology of BOO in men with BPH has been attributed to both static (prostatic tissue) and dynamic (smooth muscle) factors. BPH is a diagnosis based on histological findings of proliferating stromal and epithelial cells within the prostatic transition zone. The exact etiology of BPH is unclear; however, much epidemiological evidence has led to the hypothesis that a sex steroid imbalance and an inflammatory process are the key drivers of not only the development but also the progression of BPH (Fibbi et al., 2010; Vignozzi et al., 2014).

Testicular androgens are required in the prostate for the development of BPH. The enzyme steroid 5 α -reductase 2 which is bound to the nuclear membrane, converts testosterone into dihydrotestosterone (DHT), the principal androgen in the prostate accounting for 90% of total prostatic androgen. Testosterone and its derivatives interact with the androgen receptor (AR), which upon binding translocates to the nucleus and binds to the androgen response element (ARE), promoting the expression of genes encoding various growth factors (including keratinocyte growth factor (KGF), epidermal growth factor (EGF) and insulin-like growth factors (IGFs). In stromal cells, most of the testosterone is converted to dihydrotestosterone (DHT), which then acts in an autocrine manner to promote stromal proliferation. DHT can also diffuse into the adjacent epithelial cell to act in a paracrine manner. DHT produced peripherally in the liver and the skin can also diffuse from the circulation into the prostate to act in an endocrine manner. BPH probably develops as a result of an imbalance between mechanisms that regulate cell death and cell proliferation. Growth factors such as KGF, EGF, and IGFs, which are AR target genes, are probably involved, as is transforming growth factor- β (TGF β), which is negatively regulated by androgens (Chughtai et al., 2016; Roehrborn, 2008).

The metabolic syndrome influences LUTS–BPE development and progression, having direct inflammatory effects within the prostate (Vignozzi et al., 2014). By acting as antigen-presenting cells or as targets of Toll-like receptor agonists, prostatic stromal cells can actively contribute to the prostate-specific inflammatory process, resulting in the production of proinflammatory cytokines and chemokines, which perpetuate chronic inflammation (Vignozzi et al., 2014). Activation of Toll-like receptors and production of proinflammatory chemokines, such as IL-6 and IL-8, further promote prostate cell hyperplasia through direct proliferative action of IL-8 or through the release of other growth factors, such as FGF-2 (Vignozzi et al., 2014). Activated prostatic cells

also stimulate CD4+ lymphocyte proliferation and prompt their differentiation towards a TH1/TH17 phenotype, which shifts an acute inflammatory response towards a chronic autoimmune inflammatory disease (Vignozzi et al., 2016).

Bladder Structure and Function

The bladder is sensitive to prostatic conditions. BOO caused by BPH has been shown to affect bladder structure and function. The response of the bladder to obstruction is primarily an adaptive one. Initially, BOO can lead to the development of smooth muscle hypertrophy in the bladder^{62,63}, which is associated with intracellular and extracellular changes in smooth muscle cells (Levin et al., 2000). Such changes may lead to detrusor overactivity and decreased compliance, resulting in patients experiencing symptoms of frequency and urgency as well deterioration in the strength of the urinary stream and incomplete emptying. Trabeculation (thickening) of the bladder wall is the predominant endoscopic finding in these patients.

Diagnostic Evaluation

As BPH is a common condition affecting a considerable proportion of men, screening and prevention of the disease are not pertinent.

Several key diagnostic tools and investigations are used to diagnose BPH in men who present with LUTS. The European Association of Urology and the American Urological Association have published guidelines for the investigation of LUTS related to BPH (European Association of Urology, 2016; Gratzke et al., 2015; McVary et al., 2011).

Medical History

The importance of assessing the patient's history is well recognized. The aim of obtaining a medical history is to identify potential causes of LUTS and relevant comorbidities, such as medical (e.g., diabetes mellitus or insipidus, renal disease, heart failure, sleep apnoea) and neurological diseases. It is useful to review current medication, and assess lifestyle habits, as well as emotional and psychological factors. Potential erectile and other forms of sexual dysfunction should be investigated (validated symptom questionnaires are helpful).

Symptom Score Questionnaires

Symptom scores are helpful in quantifying LUTS and in identifying which type of symptoms are predominant, yet they are not disease-, or age-specific. Several questionnaires are available (International Prostate Symptom Score IPSS, International Consultation on Incontinence Questionnaire ICIQ-MLUTS, Danish Prostate Symptom Score DAN-PSS, AUA Symptom Score), all of which are sensitive to symptom changes and treatment monitoring.

Frequency Volume Charts and Bladder Diaries

The recording of volume and time of each void by the patient is referred to as a frequency volume chart (FVC). Inclusion of additional information such as fluid intake, use of pads, activities during recording, or symptom scores is termed a bladder diary (Abrams et al., 2002). Parameters that can be derived from the FVC and bladder diary include: daytime and night-time voiding frequency, total voided volume, the fraction of urine production during the night (nocturnal polyuria index), and volume of individual voids.

Physical Examination and Digital-Rectal Examination (DRE)

A physical examination should be performed, particularly focusing on the urinary tract. The suprapubic region should be examined for signs of bladder distension. The penis should be examined for evidence of phimosis, meatal stenosis or abnormal penile lesions.

A neurological examination should also be performed on the lower limbs to rule out a possible underlying neurological condition that might result in urinary symptoms. A DRE should be performed on all patients with LUTS. A DRE facilitates the estimation of prostate volume and can also assess the shape and consistency of the prostate and identify the presence of firm or hard areas or nodules, which can raise suspicions of prostate cancer.

Urinalysis

Urinalysis (dipstick or sediment) is an inexpensive test that must be incorporated in the primary evaluation of any patient presenting with LUTS to determine conditions such as urinary tract infection and diabetes mellitus on the basis of abnormal findings (haematuria, proteinuria, pyuria, glucosuria, ketonuria, positive nitrite test). There is limited evidence, yet general expert consensus that the benefits outweigh the costs.

Prostate-Specific Antigen (PSA)

The level of PSA has been shown to reflect prostate volume. The higher the PSA level, the greater the likelihood of an enlarged prostate—with a 69% chance of having a prostate volume of > 40 mL with a PSA level of 4.1–7.0 ng per mL (Bohnen et al., 2007). However, PSA testing should not be routine; the benefits and risks of testing should be discussed with the patient. In particular, the test is used in prostate cancer diagnostics, therefore, the possibility of a need for a prostate biopsy and associated risks should be discussed. The European Association of Urology recommends that PSA testing should only be performed if it can assist in decision making in patients at risk of BPH progression.

Renal Function Measurement

Renal function may be assessed by measurement of serum creatinine or calculation or determination of the estimated glomerular filtration rate (eGFR). Hydronephrosis, renal insufficiency, and urinary retention appear with greater prevalence in patients with symptoms or signs of BPO. In addition, patients with renal insufficiency have a higher risk of developing postoperative complications compared to those with normal renal function.

Uroflowmetry and Postvoid Residual Urine (PVR)

Urinary flow rate assessment is a basic noninvasive urodynamic test that is widely used to evaluate LUTS. Key parameters are $Q_{\max}$, voided volume, and flow pattern. Uroflowmetry parameters should ideally be evaluated when the voided volume is > 150 mL. It is recommended that at least two flow rates should be obtained. The diagnostic accuracy of uroflowmetry for detecting BOO varies considerably and is substantially influenced by diagnostic threshold values. A $Q_{\max}$ threshold of 10 mL/s had specificity of 70%, PPV of 70%, and sensitivity of 47% for BOO; thus, uroflowmetry alone is unsuitable for detection and quantification of BOO. Low $Q_{\max}$ can arise as a consequence of BOO, detrusor underactivity, or an underfilled bladder. Thus, uroflowmetry is limited as a diagnostic test because of the inability to discriminate underlying mechanisms in men with low $Q_{\max}$. Specificity can be improved by repeated flow-rate testing in individual patients. Uroflowmetry can be used to monitor treatment outcomes and correlate symptoms with objective findings.

Postvoid residual urine (PVR) can be measured by transabdominal ultrasonography, a bladder scan, or catheterization. The AUA states that determination of the PVR volume is optional in the initial diagnostic assessment and during subsequent monitoring as a safety parameter, whereas the EAU guidelines state that measurement of PVR volume in men with LUTS should be a routine part of the assessment (European Association of Urology, 2016; Gratzke et al., 2015; McVary et al., 2011).

Imaging

The routine use of upper tract imaging is not recommended for patients with BPH (European Association of Urology, 2016; Gratzke et al., 2015; McVary et al., 2011); however, it might be helpful in patients who have a urinary tract infection, urolithiasis, renal insufficiency and/or haematuria. Patients with LUTS and haematuria should be investigated. The prostate can be imaged by several modalities including TRUS, CT and MRI (European Association of Urology, 2016). TRUS or transabdominal ultrasonography are the most easily performed, although TRUS is more accurate for assessing prostate volume. TRUS is also useful in determining the degree of intravesical prostatic protrusion, which is the distance between the bladder neck and the tip of the prostate median lobe. The degree of intravesical prostatic protrusion has been shown to correlate with the severity of BOO on urodynamics. Routine use of urethrocystoscopy is not required for patients with uncomplicated LUTS (which include those without a history of urinary tract infections, haematuria, bladder stones, predominantly irritative symptoms or a secondary pathology such as bladder cancer) according to the AUA (McVary et al., 2011). Evaluation of a prostatic middle lobe in urethrocystoscopic findings is necessary to determine the indication for certain interventional treatments (European Association of Urology, 2016).

Urodynamics and Video-Urodynamics

In male LUTS, the most widespread invasive urodynamic techniques employed are filling cystometry and pressure flow studies (PFS). The major goal of urodynamics is to explore the functional mechanisms of LUTS and to identify risk factors for adverse outcomes (for informed/shared decision-making). Although urodynamic pressure–flow investigations are a second line studies, they might be necessary to measure the relative contribution of the bladder and the prostate to lower urinary tract dysfunction. Pressure–flow studies are the only method to determine if LUTS are due to BOO or due to an underactive detrusor. The EAU recommends that men < 50 years of age or those > 80 years of age who are being considered for surgery should undergo pressure–flow studies. If a patient had a previous unsuccessful surgical treatment for BPH, pressure–flow studies should be performed to assess detrusor function (European Association of Urology, 2016; Gratzke et al., 2015).

Videourodynamics (synchronous x-ray imaging and filling of the bladder with contrast medium for cystometry and PFS) may be used when there is uncertainty regarding the mechanisms of voiding LUTS. The test provides additional anatomical information.

Disease Management

Treatment options for men with LUTS start at watchful waiting and progress through medical to surgical interventions.

Conservative Treatment: Watchful Waiting, Behavioral and Dietary Modifications

Many men with LUTS are not troubled enough by their symptoms to need drug treatment or surgical intervention. All men with LUTS should be formally assessed prior to any allocation of treatment in order to establish symptom severity and to differentiate between men with uncomplicated (the majority) and complicated LUTS. Watchful waiting includes advice about lifestyle changes that can help to ameliorate or circumvent symptoms. These changes include advice about volume, type and timing of liquids consumed, avoidance of caffeine (a diuretic), abstinence of alcohol consumption in the evening and regulation of bowel movements with avoidance of constipation ([European Association of Urology, 2016](#)).

Pharmacological Treatment

The aim of medical therapy is to improve symptoms, lower the risk of progression and improve quality of life. Guidelines and algorithms are available to help selection ([European Association of Urology, 2016](#)).

- *α 1-Adrenoceptor antagonists (α 1-blockers)* ([European Association of Urology, 2016](#)). The medical therapies target are adrenergic receptor subtypes: α 1A-adrenoceptor which is the predominate receptor in prostate stromal smooth muscle and bladder neck, α 1B-adrenoceptor and the α 1D-adrenoceptor. Blockade adrenoceptors results in smooth muscle relaxation and subsequent improvement in the passage of urine. α 1-blockers are often considered the first line drug treatment of male LUTS because of their rapid onset of action, good efficacy, and low rate and severity of adverse events ([Lepor, 2007](#)). However, α 1-blockers do not prevent occurrence of urinary retention or need for surgery. Ophthalmologists should be informed about α 1-blocker use prior to cataract surgery. Elderly patients treated with nonselective α 1-blockers should be informed about the risk of orthostatic hypotension. Sexually active patients treated with selective α 1-blockers should be counseled about the risk of retrograde ejaculation.
- *5 α -reductase inhibitors* ([European Association of Urology, 2016](#)). Two 5 α -reductase inhibitors (5-ARIs) are available for clinical use: dutasteride and finasteride. Finasteride inhibits only 5 α -reductase type 2, whereas dutasteride inhibits 5 α -reductase types 1 and 2 with similar potency (dual 5-ARI). 5-ARIs act by inducing apoptosis of prostate epithelial cells leading to prostate size reduction of about 18%–28% and a decrease in circulating PSA levels of about 50% after 6–12 months of treatment. Treatment with 5-ARIs should be considered in men with moderate-to-severe LUTS and an enlarged prostate (> 40 mL) and/or elevated PSA concentration (> 1.4–1.6 ng/mL). 5 α -reductase inhibitors can prevent disease progression with regard to acute urinary retention and the need for surgery. Due to the slow onset of action, they are suitable only for long-term treatment (years). Their effect on the serum PSA concentration needs to be considered in relation to PCA screening.
- *Muscarinic receptor antagonists (antimuscarinics) and Beta-3 agonist* ([European Association of Urology, 2016](#)). Muscarinic receptors are involved in the modulation of detrusor contractility; inhibition of these receptors reduces smooth muscle tone and relieves filling phase symptoms. In the human detrusor M2 and M3 receptors are predominant (M2:M3 ratio 3:1, but the M3 subtype is functionally more important). Available agents include nonselective antagonists, such as oxybutynin, and selective antagonists, such as solifenacin and tolterodine ([Abrams et al., 2006](#)). Not all antimuscarinics have been tested in elderly men, and long-term studies on the efficacy of muscarinic receptor antagonists in men of any age with LUTS are not yet available. In addition, only patients with low PVR volumes at baseline were included in the studies. These drugs should therefore be prescribed with caution, and regular reevaluation of IPSS and PVR urine is advised. Men should be advised to discontinue medication if worsening voiding LUTS or urinary stream is noted after initiation of therapy. For patients who have a poor response to anti-muscarinic drugs or who have previously experienced adverse effects with these drugs, agonism of the β 3-adrenoceptor might be an alternative treatment option ([Thiagamoorthy et al., 2016](#)). Beta-3 adrenoceptors are the predominant beta receptors expressed in the smooth muscle cells of the detrusor and their stimulation is thought to induce detrusor relaxation. Indeed, mirabegron has recently been made available for men with moderate-to-severe LUTS who mainly have bladder storage symptoms in the United States and Europe.
- *Phosphodiesterase 5 inhibitors (PDE5Is)* ([European Association of Urology, 2016](#)). Phosphodiesterase type 5 (PDE5) negatively regulates smooth muscle contraction by hydrolysing cGMP (which is crucial to muscle relaxation via its effects on intracellular calcium levels). Accordingly, inhibition of PDE5 leads to the relaxation of smooth muscle in the bladder neck, urethra and prostate ([Gacci et al., 2012](#)). To date, only tadalafil 5 mg once daily has been officially licensed for the treatment of male LUTS with or without ED. The meta-regression suggested that younger men with low body mass index and more severe LUTS benefit the most from treatment with PDE5Is. There is limited information on reduction of prostate size and no data on disease progression.
- *Plant extracts—phytotherapy* ([European Association of Urology, 2016](#)). Herbal drug preparations are made of roots, seeds, pollen, bark, or fruits. There are single plant preparations (mono-preparations) and preparations combining two or more plants in one pill (combination preparations). The most widely used plants are *Cucurbita pepo* (pumpkin seeds), *Hypoxis rooperi* (South African star grass), *Pygeum africanum* (bark of the African plum tree), *Secale cereale* (rye pollen), *Serenoa repens* (syn. Sabal serrulata; saw palmetto) and *Urtica dioica* (roots of the stinging nettle). Nowadays, there are not any specific

recommendations on phytotherapy for the treatment of male LUTS due to product heterogeneity, a limited regulatory framework, and methodological limitations of the published trials and meta-analyses.

- *Combination therapies* (European Association of Urology, 2016). Compared with α 1-blockers or 5-ARI monotherapy, combination therapy results in a greater improvement in LUTS and increase in $Q_{\max}$ and is superior in prevention of disease progression. However, combination therapy is also associated with a higher rate of adverse events. Combination therapy should therefore be prescribed primarily in men who have moderate-to-severe LUTS and are at risk of disease progression (higher prostate volume, higher PSA concentration, advanced age, higher PVR, lower $Q_{\max}$, etc.). Combination therapy should only be used when long-term treatment (more than 12 months) is intended and patients should be informed about this. Discontinuation of the α 1-blocker after 6 months might be considered in men with moderate LUTS (Roehrborn et al., 2010). Combination treatment of an α 1-blocker with a muscarinic receptor antagonist is helpful in patients with moderate-to-severe LUTS if relief of storage symptoms has been insufficient with monotherapy with either drug (Filson et al., 2013). However, measuring PVR is recommended during combination treatment.

Surgical Treatment

Many surgical options are available for men with BPH. Surgical treatment is usually required when patients have experienced recurrent or refractory urinary retention, overflow incontinence, recurrent UTIs, bladder stones or diverticula, treatment-resistant macroscopic haematuria due to BPH/BPE, or dilatation of the upper urinary tract due to BPO, with or without renal insufficiency (absolute operation indications, need for surgery).

Additionally, surgery is usually needed when patients have not obtained adequate relief from LUTS or PVR using conservative or medical treatments (relative operation indications). The choice of surgical technique depends on prostate size, comorbidities of the patient, ability to have anesthesia, patients' preferences, willingness to accept surgery-associated specific side-effects, availability of the surgical armamentarium, and experience of the surgeon with these surgical techniques.

- *Transurethral resection of the prostate (TURP) and transurethral incision of the prostate (TUIP)* (European Association of Urology, 2016). TURP removes tissue from the transition zone of the gland. TUIP involves incising the bladder outlet without tissue removal. This technique may replace TURP in selected cases. TURP and TUIP are effective treatments for moderate-to-severe LUTS secondary to BPO. The choice should be based primarily on prostate volume (<30 mL and 30–80 mL suitable for TUIP and TURP, respectively). No studies on the optimal cut-off value exist but the complication rates increase with prostate size. Bipolar TURP (B-TURP) addresses a major limitation of monopolar TURP (M-TURP) by allowing performance in normal saline. The choice of B-TURP should be based on equipment availability, surgeon's experience, and patient's preference.
- *Open prostatectomy* (European Association of Urology, 2016). It is the oldest surgical treatment for moderate-to-severe LUTS secondary to BPO. Obstructive adenomas are enucleated using the index finger, approaching from within the bladder (Freyer procedure) or through the anterior prostatic capsule (Millin procedure). It is used for substantially enlarged glands (>80–100 mL). Open prostatectomy is the most invasive surgical method but it is an effective and durable procedure for the treatment of LUTS/BPO. In the absence of an endourological armamentarium including a holmium laser or a bipolar system, OP is the surgical treatment of choice.
- *Laser treatments of the prostate* (European Association of Urology, 2016). Different types of lasers are available: holmium:yttrium-aluminium garnet (Ho:YAG) laser, the 532 nm (Greenlight) laser, Diode laser, Thulium:yttrium-aluminium-garnet laser. Laser operations are surgical procedures that require experience and relevant endoscopic skills. The experience of the surgeon is the most important factor affecting the results and the overall occurrence of complications. In general, follow-up data showed efficacy and safety outcomes similar to TURP but long term results are pending.
- *Prostatic stents* (European Association of Urology, 2016). A prostatic stent requires a functioning detrusor. Permanent stents are biocompatible, allowing for epithelialisation. Temporary stents do not epithelialise and may be either biostable or biodegradable. Temporary stents can provide short-term relief from BPO in patients temporarily unfit for surgery, or after minimally invasive treatment. Due to common side effects and a high migration rate, prostatic stents have a limited role in the treatment of moderate-to-severe LUTS. Temporary stents can provide short-term relief from LUTS secondary to BPO in patients temporarily unfit for surgery or after minimally invasive treatment.
- *Prostatic urethral lift* (European Association of Urology, 2016). The prostatic urethral lift (PUL) represents a novel minimally invasive approach under local or general anesthesia. Encroaching lateral lobes are compressed by small permanent suture-based implants delivered under cystoscopic guidance (Urolift[®]) resulting in an opening of the prostatic urethra that leaves a continuous anterior channel through the prostatic fossa ranging from the bladder neck to the verumontanum. Long-term studies are needed to evaluate the duration of the effect in comparison to other techniques.

Glossary

5-Alpha reductase Enzyme responsible for the conversion of testosterone to its biologic active form (dihydrotestosterone).

Dihydrotestosterone Biologic active form of testosterone

Prostate-specific antigen (PSA) Is a member of the kallikrein-related peptidase family and is secreted by the epithelial cells of the prostate gland.

Testosterone The primary male sex hormone produced by the testis and in the adrenal cortex

Overview

Prostate cancer is the leading cancer (29% of all cancers) and the third most common cause of cancer-related death in men in the United States. It is estimated 1 in 7 men will develop prostate cancer in their lifetimes and 1 in 38 will die of prostate cancer. Although prostate cancer can be a lethal disease, most men diagnosed with prostate cancer do not die from it. Indeed, the overall 5-, 10-, and 15-year survival rates are 100%, 98%, and 95%, respectively. Several risk factors associated with the development of prostate cancer have been described:

- Age: Older age is associated with prostate cancer. Only 1 in 10,000 under age 40 will be diagnosed with prostate cancer, compared to 1 in 39 for ages 40–59, 1 in 14 for ages 60–69.
- Race and ethnicity: African-American and Caribbean men of African ancestry have a higher risk of being diagnosed with prostate cancer. African-American men are also more likely to die of prostate cancer than Caucasian men.
- Family history and genetics: Prostate cancer risk increases according to the number of family members with prostate cancer, degree of relatedness, and the age at which they were diagnosed. For example, the risk of prostate cancer is doubled when the father is affected compared to a 5-fold increased risk when more than 2 first-degree relatives are diagnosed with cancer. Moreover, several prostate cancer susceptibility genes have been proposed including BRCA1, BRCA2, and HNPCC genes.
- Other factors: diet, obesity, lifestyle, and chemical exposures have been suggested as potential risk factors but the evidence is less clear. Some studies suggested a link between vasectomy and higher risk of prostate cancer, but this has been debunked by recent evidence showing no association.

Data on prostate cancer prevention is sparse. Five-alpha reductase inhibitors have been shown to reduce the overall risk of prostate cancer, but there were concerns about increase in the incidence of more aggressive tumors and mortality data is unknown. Diet and lifestyle have been proposed as potential areas where preventive measures could be developed, but so far there is no definitive evidence of a protective effect of lifestyle and dietary changes (Lee et al., 2017).

By far, the most common histological type of prostate cancer is adenocarcinoma. Prostate adenocarcinomas are typically composed of small glands that are back to back, with little or no intervening stroma. Cytologic changes include enlarged round, hyperchromatic nuclei that have a single prominent nucleolus. Less differentiated carcinomas have fused glands, solid nests, or sheets of tumor cells, and many tumors have two or more of these patterns. Prostate cancer is graded according to the Gleason grading system based on the pattern of growth. There are 5 grades (from 1 to 5) based upon the architectural patterns. The two most common patterns are reported and added to calculate the final score (ranging from 2 to 10).

Detection

Most patients with early prostate cancer are asymptomatic. In some cases, however, prostate cancer can cause local symptoms including obstructive and irritative urinary symptoms such as weak stream, increased urinary frequency, and dysuria, as well as hematuria. The presence of symptoms often suggests locally advanced disease as these can be the results of direct local invasion of the cancer into the urethra and/or bladder. Metastatic prostate cancer to the bone can cause pain and predispose patients to fractures. Although early prostate cancer typically has no signs on physical exam, abnormal digital rectal exam (DRE) such as the presence of induration or nodule in the prostate are the most common physical exam findings suggestive of prostate cancer.

Given the lack of reliable symptoms and signs to detect early prostate cancer, most cases are detected based on abnormal prostate-specific antigen (PSA). PSA is a member of the human kallikrein proteins, primarily secreted in the seminal fluid by the epithelial cells of the prostate acini. It is produced for the ejaculate and is responsible for liquifying the semen and potentially dissolving the cervical mucus allowing the free movement of sperm. PSA is present in small quantities in the serum in both bound and unbound forms that can be measured. Serum PSA levels vary with age, race, and prostate volume. In addition, prostate

inflammation, infection, and cancer can cause PSA to rise. On average, 30% of patients with elevated PSA have prostate cancer diagnosed on biopsy.

Prostate cancer screening with PSA and DRE has been the topic of much debate. Although the disease is theoretically ideal for screening given its long presymptomatic phase, accurate diagnostic tests, and effective treatment options, two large randomized trials have questioned the efficacy of screening in reducing cancer mortality. Most medical societies recommend a risk-stratified approach to prostate cancer screening where age, family history, and life expectancy should be taken into consideration.

Prostate biopsy is the most frequently employed technique to detect prostate cancer. The two most common approaches are transrectal and transperineal. Both approaches are typically guided by transrectal ultrasound which allows a uniform spatial separation and sampling of the regions of the prostate. Although there are several variations, most biopsy schemes sample the apex, mid-gland, and base of both right and left prostate lobes. Axial imaging of the prostate, especially magnetic resonance (MRI), has been gaining a bigger role in the management of prostate cancer. For example, MRI can identify suspicious lesions in the prostate that can be targeted by biopsies or focal treatments as well as aid in local staging by identifying signs of extraprostatic extension, seminal vesicle invasion, and enlarged lymph nodes. X-ray, CT scan, and nuclear medicine bone scan are used for the diagnosis of metastatic disease.

The natural history of prostate cancer is very heterogeneous. While some tumors have a slow and indolent disease course, others have a quick and aggressive progression leading to metastasis and death. Thus, it is important to risk stratify patients to determine patients who have a high-risk disease and may benefit from more aggressive management including radiotherapy and surgery and those who have low-risk disease and may potentially benefit from a watchful waiting and surveillance. Multiple risk stratification schemes have been described. Most of these schemes rely on clinical information such as the PSA, Gleason grade, and clinical staging including physical examination and imaging. Biomarkers based on gene expression of the tumor sample obtained on biopsy is an emerging area of research for risk stratification. The TNM staging system for prostate cancer, which correlates with the risk of disease progression, is presented in **Tables 1** and **2**. Of note, the stage is divided into clinical (based on clinical parameters such as digital rectal exam, PSA, and imaging) and pathological (based on pathology of the prostate gland after radical prostatectomy).

Table 1 Prostate cancer TNM staging

Stage	Clinical	Pathological
Primary tumor (T)		
Tx	Primary tumor cannot be assessed	No evidence of primary tumor
T0	No evidence of primary tumor	
T1	Clinically inapparent tumor neither palpable nor visible by imaging	
T1a	Tumor incidental histologic finding in 5% or less of tissue resected	
T1b	Tumor incidental histologic finding in more than 5% of tissue resected	
T1c	Tumor identified by needle biopsy (for example, because of elevated PSA)	Organ confined Unilateral, one-half of one side or less Unilateral, involving more than one-half of side but not both sides Bilateral disease Extraprostatic extension or seminal vesicle invasion Extraprostatic extension or microscopic invasion of bladder neck Seminal vesicle invasion Invasion of rectum, levator muscles, and/or pelvic wall
T2	Tumor confined within prostate	
T2a	Tumor involves one-half of one lobe or less	
T2b	Tumor involves more than one-half of one lobe but not both lobes	
T2c	Tumor involves both lobes	
T3	Tumor extends through the prostate capsule	
T3a	Extracapsular extension (unilateral or bilateral)	
T3b	Tumor invades seminal vesicle(s)	
T4	Tumor is fixed or invades adjacent structures other than seminal vesicles, such as external sphincter, rectum, bladder, levator muscles, and/or pelvic wall	
Regional lymph nodes (N)		
NX	Regional lymph nodes were not assessed	Regional nodes not sampled
N0	No regional lymph node metastasis	No positive regional nodes
N1	Metastasis in regional lymph node(s)	Metastases in regional node(s)
Distant metastasis (M)		
M0	No distant metastasis	
M1	Distant metastasis	
M1a	Nonregional lymph node(s)	
M1b	Bone(s)	
M1c	Other site(s) with or without bone disease

Table 2 Prostate cancer TNM staging

Groups	T	N	M	PSA	Gleason
I	T1a-c	N0	M0	PSA < 10	Gleason ≤ 6
	T2a	N0	M0	PSA < 10	Gleason ≤ 6
	T1-2a	N0	M0	PSA unknown	Gleason unknown
IIA	T1a-c	N0	M0	< 20	Gleason 7
	T1a-c	N0	M0	10 ≥ PSA < 20	Gleason ≤ 6
	T2a	N0	M0	10 ≥ PSA < 20	Gleason ≤ 6
	T2a	N0	M0	PSA < 20	Gleason 7
	T2b	N0	M0	PSA < 20	Gleason ≤ 7
	T2b	N0	M0	PSA unknown	Gleason unknown
IIB	T2c	N0	M0	Any PSA	Any Gleason
	T1-2	N0	M0	PSA ≥ 20	Any Gleason
	T1-2	N0	M0	Any PSA	Gleason ≥ 8
III	T3a-b	N0	M0	Any PSA	Any Gleason
IV	T4	N0	M0	Any PSA	Any Gleason
	Any T	N1	M0	Any PSA	Any Gleason
	Any T	Any N	M1	Any PSA	Any Gleason

Treatment

Treatment decisions for prostate cancer are based on tumor aggressiveness (e.g., grade), stage, patient's life expectancy, and the ability of each therapy to ensure disease-free survival, maximizing quality-of-life while minimizing side effects. Localized prostate cancer is typically treated with active surveillance, radical prostatectomy, radiotherapy, or focal therapies. Metastatic prostate cancer is usually treated with systemic therapies. Given some of these therapies may interfere with fertility by either reducing or abolishing spermatogenesis and/or blocking sperm transport, some patients may be candidates for sperm banking before the initiation of treatment.

Watchful Waiting

Patients with prostate cancer are often older and many have comorbidities. Moreover, several prostate tumors have a very long and indolent course. Many untreated patients with prostate cancer die of causes other than prostate cancer. This raises the question of whether some patients with prostate cancer should be treated, especially considering that many treatments pose risks and side effects. The watchful waiting strategy involves deferring treatment until the patient becomes symptomatic due to local symptoms or metastatic disease. It aims at maintaining quality of life while avoiding side effects. It is an appropriate treatment choice for older patients with limited life expectancy and indolent tumors.

Active Surveillance (AS)

AS involves actively monitoring the course of prostate cancer with the expectation to deliver curative treatment if and when the disease progresses. It typically involves the use of serial prostate biopsies to monitor prostate cancer grade and volume in order to identify disease progression. Different from watchful waiting, AS is an appropriate treatment for younger patients with seemingly indolent disease with the goal to defer treatment and its potential side effects. Patients should be followed closely and treatment (typically surgery, radiation, or focal therapies) should start promptly when the cancer progresses to avoid missing the chance for cure.

Radical Prostatectomy (RP)

RP involves the surgical removal of the entire prostate and seminal vesicles. When indicated, a pelvic lymphadenectomy is done at the same time. There are several surgical approaches including open retropubic, open transperineal, laparoscopic, and robot-assisted. RP is considered an appropriate therapy for patients with clinically localized prostate cancer that can be completely excised surgically, who have life expectancy greater than 5 years and have no serious comorbidities that would contraindicate an elective operation. The most common risks and side effects associated with this procedure include bleeding, infection, damage to nearby structures, urinary incontinence, and erectile dysfunction. The prognosis of patients treated with RP depends on the pathological stage and grade. For example, patients with organ-confined disease have a 70%–85% disease-free survival at 10 years compared to 20%–30% for those with extraprostatic extension and positive surgical margins.

Radiotherapy

Radiotherapy involves the delivery of high-energy radiation to treat disease. It can be given both externally (external beam radiation) and/or internally (brachytherapy). Prior to treatment, the prostate is mapped using imaging tests (CT or MRI scan) and a treatment plan (simulation) is established. The most commonly used techniques of external beam radiation include

three-dimensional conformal radiotherapy (radiation beams are then shaped and aimed at the prostate from several directions), intensity-modulated radiotherapy (the intensity of the beams is adjusted to limit the doses reaching nearby normal tissues), and proton beam radiotherapy. Brachytherapy can be delivered permanently (low-dose) by placing radioactive pellets in the prostate, or temporally (high-dose) by placing where radioactive needles in the prostate for only a few moments and then removing them. Androgen deprivation therapy for a few months is typically given along with radiotherapy. The most common side effects of radiotherapy for prostate cancer include radiation proctitis, radiation cystitis, urethral stricture, and erectile dysfunction. The prognosis of patients treated with radiotherapy is comparable to those treated with RP when matched by pathological stage and grade.

Focal Therapies

The rationale for focal therapies of the prostate is to treat the tumor while sparing the normal prostate. Although there are several means of delivering energy to kill the tumor, the most used technique is cryotherapy. Freezing of the prostate is accomplished by using a multiprobe cryosurgical device. Multiple probes are placed percutaneously under transrectal ultrasound guidance, and the temperature is lowered to -25 to -50°C . Potential side effects include recurrence/persistence of the cancer in the untreated prostate, hematuria, urinary incontinence, erectile dysfunction, and injury to surrounding structures. Although short-term studies showed promising results, long-term oncologic results are unknown.

Systemic Therapies

Several systemic agents are available to treat prostate cancer. These treatments are commonly used for locally advanced and metastatic disease.

Androgen Deprivation Therapy (ADT)

Androgens are required for normal growth and function of the prostate. They also stimulate prostate cancer cells growth. Lowering androgen levels or stopping them from getting into prostate cancer cells often makes prostate cancer to shrink or grow more slowly for a time. ADT is currently the initial treatment for metastatic prostate cancer. Although most tumors respond to ADT in the beginning, over the course of months to years most tumors become refractory to ADT and are called castration-resistant prostate cancer (CRPC). Several types of ADT can be used to treat prostate cancer:

- Bilateral orchiectomy (surgical castration): removes 95% of the testosterone which is produced by the testicles. It does not suppress the androgens produced by adrenal or by peripheral conversion of other steroids.
- Luteinizing hormone-releasing hormone (LHRH) agonists and antagonists: by blocking the release or action of LHRH these drugs inhibit luteinizing hormone and consequently the production of testosterone by the testicles. Currently, these are the most prescribed ADT for prostate cancer.
- CYP17 inhibitors: block CYP17A1 enzymes that are expressed in the testicle, adrenal, and prostate tumors causing a decrease in circulating and tissue levels of androgens such as dehydroepiandrosterone (DHEA), testosterone, and dihydrotestosterone (DHT).
- Antiandrogens: are a class of drugs that blocks the androgen receptor (AR). By competing for binding to the androgen receptor, antiandrogens reduce the ability of androgens to promote prostate cancer cell growth. They are frequently used in combination with orchiectomy or a LHRH agonist or antagonist (called combined androgen blockade or total androgen blockade).
- Estrogens: Although estrogens are also able to inhibit testosterone production by the testicles, they are rarely used today because of their side effects.

Chemotherapy

The use of cytotoxic chemotherapy is usually used in cases of metastatic disease, especially CRPC. The most commonly prescribed drugs are: docetaxel, cabazitaxel, mitoxantrone, and estramustine.

Immunotherapy

Several immunomodulatory agents are being investigated. Currently only Sipuleucel-T is approved for the treatment of metastatic prostate cancer. It works through activating antigen-presenting cells to stimulate T-cell immune response targeted against prostatic acid phosphatase, an antigen that is highly expressed in most prostate cancer cells.

Testicular Cancer

Hari T Vigneswaran and Michael Abern, University of Illinois Hospital and Health Sciences System, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Background

Although a rare tumor in the general population, testicular cancer is the most common solid organ cancer in males aged 15–44. Testicular cancer can often be treated successfully, with five-year survival of 99% for tumors localized to the testicle and 96% for cancer spread to regional retroperitoneal lymph nodes. Testicular cancer treatment has served as a model for the utilization of the multi-modal and multi-disciplinary care of cancer. Since the discovery of platinum-based chemotherapy in the 1980s, cure rates for advanced testicular cancer have increased from 5% to as high as 90%, when cure is defined as cancer remission for 5 years or greater. However, with advancements in treatment and therefore improved survival, due to their young age patients are at risk for long-term treatment induced toxicity and fertility concerns.

Epidemiology and Etiology

Epidemiology

Approximately 8000 men are diagnosed with testicular cancer per year in the United States. Since 1975 the incidence of testicular cancer has increased world-wide from 2.9 per 100,000 to now 5.1 per 100,000. The highest rates in the world span the United States, Western Europe, Scandinavia, and New Zealand. Non-Asian whites are affected five times as much as blacks and four times as much as Asians and approximately 75% more than Hispanic whites. Interestingly, Hispanic whites have noted the highest increase in incidence and have been predicted to surpass the rates among non-Hispanic whites by 2026. The differences in rates observed by race and ethnicity may be in part heritable, however, the rise in incidence across all groups suggest a potential role for environmental factors as well.

Etiology

The etiology of testicular cancer is thought to be multifactorial including several known risk factors. Men with cryptorchidism are at four to six times more likely to develop cancer in the ipsilateral testicle. The risk is highest if the testis is retained intra-abdominally, less so if within the inguinal canal and further decreased risk when the patient undergoes surgical repair with orchidopexy before puberty. Interestingly, these patients also have increased risk in the contralateral descended testis. Other risk factors include a family history of testicular cancer, testicular microlithiasis, Klinefelter Syndrome, history of mumps orchitis, personal history of testicular cancer in the contralateral testis, HIV infection, and early onset of puberty, and testicular dysgenesis syndrome.

Clinical Evaluation

Presentation

The most common presentation of testicular cancer is painless swelling or a mass of the testis. However, testicular cancer can present with pain in up to 45% of patients if there is intratesticular infarction, hemorrhage, torsion of the neoplasm or simultaneous acute infection of the epididymitis. Other presentations include nodularity felt to the testicle or the sensation of fullness or ache in the scrotum. Incidental trauma to the scrotum can reveal a subtler mass which may lead to the eventual diagnosis. Signs of β -hCG-producing tumors include gynecomastia or breast tenderness in approximately 10% of patients. In certain patients, 5% of cases are detected during an evaluation for infertility. In 25% of instances, the patient can present with symptoms of disseminated cancer including back pain suggestive of retroperitoneal disease, shortness of breath, hemoptysis or chest pain suggestive of pulmonary or mediastinal disease.

Physical Exam and Scrotal Ultrasound

A thorough history and physical exam must be obtained to help differentiate a testis tumor from other causes of testicular or scrotal pathology including such as hydrocele, spermatocele, varicocele, hematocele, or epididymo-orchitis. For the evaluation of scrotal or testicular pathology the scrotal ultrasound is an extension of the physical examination. The sensitivity of ultrasound for detecting testicular cancer is approximately 96%. Ultrasound is widely available, inexpensive and noninvasive. Once visualized sonographically an intratesticular mass is testicular cancer until proven otherwise. Testicular masses can appear hypoechoic or heterogeneous, or with increased vascularity. Epididymitis is the most commonly mistaken diagnosis made when patients present with testicular cancer and delays can last several months. Delays in diagnosis can lead to stage progression and therefore the need for more aggressive treatment so it is important to have a high degree of suspicion in any man age 15–44 years with a testis mass, retroperitoneal mass, or supraclavicular mass.

Serum Tumor Markers

When testicular cancer is suspected beta-human chorionic gonadotropin (β -hCG), alpha-fetoprotein (AFP) and lactate dehydrogenase (LDH) should be measured in the serum. It is important to note that the absence of abnormal serum tumor markers does not preclude the diagnosis of testicular cancer. Typically, β -hCG levels are elevated in non-seminomatous germ cell tumors (NSGCT) with significant levels >5000 IU/L. However, approximately 20% of seminomatous GCT contain syncytiotrophoblastic cells that secrete β -hCG. Marijuana use and hypergonadotropic hypogonadism can also result in elevated β -hCG levels. The marker AFP is commonly elevated (50–70%) in embryonal and yolk sac tumors, but can also be elevated with other malignancies including hepatocellular carcinoma and pancreatic cancer. Although LDH is less specific than β -hCG and AFP, the marker is expressed on chromosome 12 and levels correlate directly to bulk of disease in GCT. While less commonly used, placental alkaline phosphatase (PLAP) is a marker for seminoma and is present in most advanced seminomas. In general tumor marker levels will vary depending on the histologic cell type and stage of disease as seen in [Table 1](#). When elevated initially serum tumor markers also have utility after orchiectomy and chemotherapy for staging and to surveil for relapse. The circulating half life of β -hCG is 24–36 h, AFP at 5–7 days, and LDH at 24 h. After a complete response to orchiectomy or chemotherapy, serum tumor markers are expected to normalize after five half lives and therefore should be measured at the appropriate time interval.

Testis Cancer Histology and Biology

Pathophysiology

Germ cells are the only cells in the body that have half the amount of chromosomes, undergo both mitosis and meiosis and in males produce the gamete, sperm. Testicular GCT make up 95% of all testicular tumors followed by sex cord tumors comprising 5%,

Most GCTs are thought to arise from precursor lesions called intratubular germ cell neoplasia (previously incorrectly classified as carcinoma in situ). These lesions may be due to arrested germ cell development which are thought to lay dormant until stimulated by increased testosterone after puberty. Although environmental factors play a role, certain genes have been associated with GCT. A commonly mutated gene called the KIT ligand gene is amplified and found in excess on Chromosome 12 with 70–80% of GCTs having an extra chromosome 12.

Histology

See [Table 1](#) for the different histological types of testicular cancer. GCT are comprised of three histologic types: seminomas (SGCT), nonseminomas (NSGCT) and spermatocytic tumors. Seminomatous and nonseminomatous tumors comprise 99% of all GCT. The seminomas are the most common type of GCT comprising approximately 65%. SGCT generally occur in older patients between 30–40s as compared to NSGCT. SGCT first arise from intratubular germ cell neoplasia and have the ability to transform into NSGCT.

NSGCT are comprised of embryonal, yolk sac, choriocarcinoma, and teratoma and mixed histologies. Mixed elements of seminomas and nonseminomas are treated as nonseminomas. Embryonal Carcinoma is the most undifferentiated cell type of NSGCT and has the potential to differentiate to teratoma and other types of NSGCTs. Although choriocarcinoma is rare, it is very aggressive, spreads hematogenously and can present with metastasis to the lung, liver, and brain. Importantly, metastatic tumor of this type are prone to hemorrhage both spontaneously and after chemotherapy. Choriocarcinoma is associated with elevated β -hCG and due to the tumor marker cross reactivity with thyroid and luteinizing receptors, sometimes patients can present with hyperthyroidism and hyperandrogenism. Yolk sac tumors (YST) primarily occur in infants when in pure form, however mixed NSGCT commonly have elements of YST. The presence of AFP is associated with YST. Teratoma contain at least two of the three embryologic germ cell layers: endoderm, mesoderm, and ectoderm. In testicular GCT these tumors can exist in matured or

Table 1 Testicular Cancer Histology

<i>Tumor type</i>	<i>Histologic sub-type</i>	<i>Frequency</i>	<i>Serum tumor markers</i>	<i>Most common age of onset</i>
Germ cell	Spermatocytic seminoma	Less than 1%	-	65
	Seminoma	65%	β -hCG	30-40
	Yolk sac	Less than 1%	AFP	Less than 10
	Choriocarcinoma	Less than 1%	β -hCG	20-30
	Embryonal	40-50%	AFP, β -hCG	25-35
	Teratoma	40-50%		25-35
Sex cord or stromal	Leydig cell	3%	Testosterone, estradiol	5-10, 30-60
	Sertoli cell	1%	Testosterone, estradiol	Any age
	Granulosa Cell	1-3%	-	Pre-pubertal
Other	Gonadoblastoma	0.5%	-	Less than 30
	Primitive neuroectodermal tumors (PNET)	Less than 1%	-	Previous diagnosis of testicular cancer

immature form, however there is no clinical difference between the two. Although teratoma appears benign on histopathology, in advanced NSGCT, metastatic teratoma is frequently found. Importantly, these metastatic tumors found in retroperitoneal lymph nodes are resistant to chemotherapy.

Sex cord or stromal cells are the supporting cells of the germ cells which help to make and transport sperm. Gonadal stromal tumors are of the leydig, sertoli, or granulosa cell type and <10% of these tumors are malignant, however presentation may be indistinguishable from GCT.

Clinical Management of Testicular Cancer

Orchiectomy

Once testicular cancer is suspected prompt diagnosis and treatment is necessary. A radical inguinal orchiectomy is typically performed within 1–2 weeks to fully remove the testicle and spermatic cord as it meets the abdominal cavity. Trans-scrotal orchiectomy and biopsy are contraindicated because this both leaves part of the spermatic cord potentially harboring cancer and alters the lymphatic drainage pattern for the testicle and cancer. Rarely, testis sparing removal of the tumor is attempted for a mass <2 cm in maximum dimension occurring in a solitary testicle, in both testicles, or when there is a high suspicion for benign histology. At the time of radical orchiectomy, a testicular prosthesis can be placed, however in children the prosthesis is placed after the completion of puberty so the proper size can be determined.

Staging

Testicular cancer staging is described using the American Joint Committee on Cancer TNMS classification (tumor, node, metastasis, and serum marker) and relies on imaging of the chest, abdomen, and pelvis, and other organs as dictated by symptoms, as well as the nadir value of the serum tumor markers post-orchiectomy. Computed tomography (CT) and magnetic resonance imaging (MRI) are commonly used imaging modalities. Positron emitted tomography (PET) scans have limited utility in testicular cancer and are generally reserved for residual masses after chemotherapy for SGCT.

Stage 1 testicular cancer is cancer confined to the testis with or without lymphatic or vascular invasion and without regional lymph node involvement. GCT follow a predictable progression of disease with via lymph drainage to the regional retroperitoneal lymph nodes. Stage 2 cancer is classified as any primary tumor with this regional lymph node invasion including the abdominal nodes that are near the aorta and the inferior vena cava at the level below the kidneys. Lastly, stage 3 describes testicular cancer that has spread beyond the primary tumor and regional lymph nodes to distant sites such as the lungs, mediastinum, bones, non-regional lymph nodes, or brain. When tumor markers persist after orchiectomy the disease is up-staged to S disease (stage 1S, 2S, 3S).

Primary Management

After orchiectomy, initial CT imaging, and serum tumor marker measurements, the stage and histology of the cancer is determined. See Fig. 1 for treatment management paradigms after orchiectomy. For Stage 1 seminoma there are primarily three options. The first option is imaging and serum marker surveillance, which requires a reliable patient and strict follow up. <20% of patients with stage 1 SGCT will relapse on surveillance. Another option is adjuvant abdominal external beam radiation therapy (XRT) to the retroperitoneal lymph nodes. Toxicity from radiation includes secondary non-GCT malignancies such as leukemia, increased risk of cardiac disease, and radiation induced kidney disease. However, after XRT the risk of relapse for stage 1 SGCT is 3%. Alternatively, one to two cycles of the chemotherapeutic, carboplatin, is available for stage 1 disease and can reduce the relapse rate to 2%. Carboplatin causes immunosuppression, nausea, fatigue, and in some instances infertility, however it is without the risk of XRT induced cardiomyopathy.

The typical chemotherapy regimen is, etoposide and cisplatin with or without bleomycin (EP or BEP). For stage 2 SGCTs with lymph nodes <5 cm in size chemotherapy with BEP or abdominal XRT to the RPLN is the indicated treatment. When either regional lymph node disease increase past 5 cm or stage 3 disease occurs a course of three BEP cycles or four EP cycles is indicated. Bleomycin can lead to pneumonitis and pulmonary fibrosis, etoposide can lead to myelosuppression, mucositis, and dose related risk of leukemia, and cisplatin can cause neuropathy, and renal and ototoxicity. SGCT are generally highly radio- and chemo-sensitive. Residual masses >3 cm, require surgical resection with RPLND (see below).

In terms of stage 1 nonseminomas, there are also three options. Active surveillance with serum testing and imaging will result in a relapse rate of approximately 30% of stage 1 NSGCT. The most predictive features of NSGCT relapse is lymphovascular invasion of the primary tumor. Adjuvant chemotherapy or primary retroperitoneal lymph node dissection (RPLND) are preferred for clinical stage 1 NSGCT thought to be at higher risk of relapse or in situations where active surveillance is not feasible. The relapse rate after two cycles of BEP is <3%, with most relapses occurring in the retroperitoneum and usually containing teratoma.

RPLND is a diagnostic and therapeutic resection of the regional lymph nodes. Ejaculatory dysfunction (ED) can occur after surgery due to the close proximity of the post ganglionic sympathetic nerves and hypogastric plexus within the field of dissection.

Fig. 1 Treatment paradigm for TNMS staging of testicular cancer.

Nerve sparing surgery can be achieved and when selected appropriately, maintains ejaculatory function in up to 99% of individuals. Apart from ED, risks of RPLND include postoperative tachycardia from sympathetic discharge, chylous ascites, vascular injury, bowel obstruction, and rarely death. The relapse rate after primary RPLND is reduced to approximately 10%. If the lymph nodes are benign or one lymph node contains a tumor focus < 2 cm in size, surveillance is preferred. More tumor involvement of the lymph nodes necessitate chemotherapy. After RPLND, most relapses occur outside of the retroperitoneum and are treated with chemotherapy.

For stage 2 NSGCTs with lymph nodes < 5 cm, either nerve sparing RPLND, a full course with 3 cycles of BEP or 4 cycles of EP chemotherapy are available options. If lymph nodes are > 5 cm (stage 2C) or serum tumor markers persist after orchiectomy (stage 1S), a full course chemotherapy is the preferred treatment. Residual retroperitoneal masses > 1 cm in size are resected with salvage RPLND. For stage 3 NSGCT, three cycles of BEP or four cycles of EP are first administered. Salvage surgical excision, including RPLND is used for residual masses > 1 cm. In stage 2C and stage 3 NSGCTs teratoma is found in approximately 35% of residual lesions, necrosis or fibrosis is found in approximately 45% of residual lesions, and malignancy are found in approximately 15% of residual lesions.

Fertility in Testis Cancer Patients

Men who are interested or undecided about fathering children are recommended to undergo cryopreservation of sperm. Cryopreservation should be done prior to radiation, RPLND, or chemotherapy. Although the etiology is not clearly identified, at the time of diagnosis of testicular cancer, approximately 50% of men are oligospermic and 10% are azoospermic, while after orchiectomy about 50% recover normospermia. Since chemotherapy is an excellent treatment for GCT, the effect on germ cells causes almost every patient to become azoospermic. If the patient had normal sperm parameters prior to treatment within 2 years of treatment completion, 50% will recover to normal levels and by years 80% of men will recover. Radiation is slightly more toxic to spermatogenesis and can take a few years longer to recover. Damage to the sympathetic nerves of ejaculation after non-nerve sparing RPLND may result in ED in 80% of patients.

Assisted Reproductive Technologies in Reproductive Medicine are presented in volume 5 throughout 82 different chapters. This volume first describes the technological process that must be developed to perform low and high complexity ART, from the drugs used for controlled ovarian stimulation, monitoring, oocyte retrieval and luteal support. Then the different technologies are presented. Hand in hand with the clinical evaluation of the male is the laboratory, as sperm is easily accessible. In the male portion of volume 5, a thorough treatment of the andrology laboratory is presented with every aspect currently measurable. Unfortunately, the great challenge of male reproductive evaluation is that while we can observe the exterior of the male gamete and some of its biological milieu, we are unable to look within the sperm to truly understand its reproductive potential. Promising technologies on the horizon include chromosomal structure, epigenetics, and Raman microspectroscopy, and these are reviewed. The volume continues with a comprehensive view of the IVF laboratory from setting, quality control and accreditation to the detailed analysis of the embryological processes from oocyte insemination, fertilization to embryo development with morphokinetics, and mechanical assessment. The genetic and epigenetic interrogation of gametes, embryos and maternal endometrium is explained in the next section. Cryobiology has revolutionized how reproductive medicine is performed nowadays, deserving a detailed analysis of cryopreservation of sperm, oocytes, embryos and ovarian tissue for both oncological and social reasons. The different current clinical strategies used in IVF, proven and unproven, that affect ovulation, endometrial receptivity and embryo transfer are also presented followed by ART in special medical conditions and possible complications, ending with the clinical follow-up of ART pregnancies and babies from prenatal screening to pediatric follow-up. Since ART treatment impose an economic burden to the infertile population, we introduce in this volume the cost-effectiveness studies of high versus low complexity reproductive treatments as well as the genetics studies associated with IVF. The support team as well as the modern ethical dilemmas and worldwide legislation in ART is then presented. The final section portrays the potential contribution of advance cell therapy, organ bioengineering, gene editing and epigenetic research in the future development of ART.

TECHNICAL PROCESSES

Mild IVF Stimulation

Introduction

It was clear to the pioneers of IVF that inefficiencies in the laboratory procedures of fertilization and embryo culture could in part be overcome by ensuring that large number of oocytes were available from each treatment cycle: indeed this was necessary in order to provide a realistic chance of generating a viable embryo for transfer into the uterus. However, generating large numbers of oocytes from a single cycle met over-riding the physiological processes that govern normal cyclic follicle recruitment and subsequent mono-follicular dominance.

This was considered to require high doses of exogenous FSH, which became duly introduced in IVF practice, with the aim of maximizing the number of oocytes obtained from a single stimulation cycle. This approach achieved some success, with higher pregnancy rates being reported in comparison to unstimulated cycles. However, it soon became apparent that such an approach came with some disadvantages. The first to be noted was the high risk of premature ovulation, arising from the high levels of estrogen generated by multiple growing follicles, thus reaching a level capable of triggering an LH surge before any of the follicles had reached maturity. In order to prevent this, it became necessary to block the LH surge. This required the down regulation of the pituitary gland for some 2 weeks prior to starting exogenous FSH, using daily injections of a GnRH agonist, which in turn resulted in menopause like symptoms as many women thus treated suffered the effects of hypoestrogenism before levels rose under FSH stimulation.

This so called "long protocol" quickly became established as the standard approach to stimulating the ovaries in order to obtain sufficient oocytes to provide a reasonable chance of obtaining an embryo for transfer. But it was long, expensive, burdensome, and exposed the patient to the potentially lethal complication of ovarian hyperstimulation syndrome, which commonly occurred.

It soon became apparent that this approach merited re-evaluation. In 1996 the founding pioneer of IVF, Robert Edwards, co-published an influential editorial making the case for this ([Edwards et al., 1996](#)).

It was argued that IVF was not simply about obtaining a positive pregnancy test at any cost, but rather this aim should be achievable without exposing the woman to excessive therapeutic burden or risk.

The call was not ignored and a number of groups started devising new approaches that sought to find the optimal balance between safety and effectiveness, based on the premise that softer stimulation would generate fewer but relatively high quality oocytes. These approaches have come to be known as mild IVF, or in cases where little or no ovarian stimulation is applied, natural cycle IVF.

The last 20 years have seen an extensive literature emerge describing the principles and practice of mild IVF, and we are now benefiting from a clearer understanding of the advantages and disadvantages of these approaches, and which patients might most benefit. In this article we will review the development of mild approaches, the debate as to their efficacy and how they might be used in clinical practice.

Mild Ovarian Stimulation in IVF

The Aim of Mild Stimulation

Essentially, mild approaches to IVF seek to find the optimal balance between producing sufficient high quality oocytes to provide a good chance of having an embryo transfer and possibly more to freeze for later use, while not producing so many as to expose the patient to unnecessary side effects, risks, and costs. The optimal number of oocytes to be obtained with this aim in mind remains subject to debate. The analysis of large databases has indicated that pregnancy rates are highest after the long protocol when 12–15 oocytes are obtained ([Van der Gaast et al., 2006](#); [Sunkara et al., 2011](#)). In contrast, a meta-analysis of studies reporting outcomes after a mild stimulation revealed the optimal number to be six to eight oocytes ([Verberg et al., 2009a](#)). It is likely the cohort of patient achieving this number after mild stimulation would have generated 15 or so oocytes after the long protocol, and that both therefore represent the optimal response to a given stimulation regimen.

The scientific principles behind the mild stimulation concept have been previously outlined ([Macklon et al., 2006](#)). As shown in [Fig. 1](#), after the inter-cycle rise in endogenous FSH has initiated cyclic recruitment of the available FSH sensitive follicles, exogenous FSH is given in doses sufficient to maintain the level above the threshold required to stimulate follicle development for a period sufficient to maintain the "FSH Window" open in order to allow six to eight follicles to reach maturity. This is contrast to the

Fig. 1 The principles of mild stimulation. In contrast the conventional stimulated cycles, mild stimulation harnesses the physiological FSH rise and supplements with exogenous FSH to maintain the level of FSH just above the necessary threshold and for the period of time necessary to allow a small number of oocytes to reach maturity. Adapted from Macklon, N. S., Stouffer, R. L., Giudice, L. C. and Fauser, B. C. (2006). The science behind 25 years of ovarian stimulation for in vitro fertilization. *Endocrine Reviews* **27**, 170–207.

traditional approach that raised FSH levels well above the required threshold level, and maintained the FSH window open long enough for all available oocytes (most of which were destined to enter atresia) to reach maturity.

The key development that made this approach possible was the clinical availability of GnRH antagonists. In contrast to GnRH agonists, these could be administered for just a short period from the mid follicular phase and still be effective in preventing a premature LH surge and loss of the oocytes prior to surgical retrieval. This meant that the spontaneous inter-cycle FSH rise was not suppressed, and could instead be harnessed to initiate follicle growth. The need for exogenous FSH to raise levels above the threshold was therefore less, and since fewer oocytes were required, the FSH window needed to be held open for a shorter period of time, requiring fewer days of injection.

One of the leading groups to develop this approach was that of Bart Fauser in Rotterdam and Utrecht. Their studies demonstrated first that it was the duration of the FSH window rather than the level of FSH above the threshold that was the key determinant of the number of oocytes to reach maturity (Schipper et al., 1998). They then showed that exogenous FSH could be delayed until day 5 of the cycle and yet still enable multi-follicle development. However, one of their key findings was that while fewer numbers of oocytes were obtained after mild stimulation, the quality of the resulting embryos was higher. This was clearly illustrated by the observation that women obtaining fewer than four oocytes after stimulation with the long protocol rarely achieved a pregnancy, whereas half of the pregnancies occurring in the mild stimulation group occurred in women who had generated less than four oocytes (Hohmann et al., 2003).

The benefits of mild stimulation on the quality of the oocytes and embryos was confirmed by a much cited study which showed the rate of chromosomal mosaicism to be less prevalent in embryos derived from mild stimulation versus the long protocol (Baart et al., 2007; Fig. 2). These studies set the scene for a large prospective randomized trial comparing a mild approach which combined lighter stimulation with single embryo transfer (SET), against the standard approach of harder, longer stimulation followed by double embryo transfer (DET). The hypothesis of this study was that the former approach could deliver the same chance of providing a healthy singleton birth within a year of starting treatment as standard approaches but with fewer complications, fewer multiple births, lower costs, and less stress to the patients. This study showed that cumulative singleton live births were not significantly different after performing four mild SET versus three conventional IVF attempts (Fig. 3). Moreover, the mild approach was shown to be associated with reduced stress and drop out from treatment. (Fig. 4). A conceptually similar 4-year clinical trial involving 564 patients who were randomized to receive mild ovarian stimulation with clomiphene and gonadotropins coupled with single embryo transfer versus conventional ovarian stimulation with the long agonist protocol coupled with (mainly) double embryo transfer was subsequently reported (Zhang et al., 2010). Although cumulative live birth rates were in favor of the conventional approach (63% vs. 49%), the very mild approach tested was also associated with the absence of OHSS, reduced rate of multiples, and reduced gonadotropin use.

Alternatives to Low Dose FSH

Clomiphene citrate is an anti-estrogen that blocks feedback at the pituitary gland causing FSH level to rise. Its advantages over FSH include its oral route of administration, low price, and widespread availability. An ovarian stimulation protocol combining CC with gonadotrophins could lead to a reduction in the amount of gonadotrophins required due to the combined synergistic

Fig. 4 The chance of not dropping out of further treatment after a failed first, second, and third cycle of IVF treatment. Those women who failed to conceive after undergoing mild stimulation IVF were more likely to continue with another cycle than those who failed after conventional ovarian stimulation. Reproduced from Verberg, M. F. G., Macklon, N. S., Nargund, G., Frydman, R., Devroey, P., Broekmans, F. J., Fauser, B. C. J. M. (2009). Mild ovarian stimulation for IVF. *Human Reproduction Update* **15**, 13–29.

effects. Additionally, because gonadotrophins may counter the anti-estrogenic effects of the CC on the endometrium which may account for the relatively low embryo implantation rates observed, this combination might lead to improved pregnancy rates compared with CC alone.

Aromatase inhibitors selectively inhibit the conversion of androgens to estrogens in granulosa cells of developing ovarian follicles, resulting in a subsequent increase in intra-ovarian androgens and absence of a rise in estrogens. Due to a reduced estrogen feedback and resulting increased endogenous gonadotrophin secretion, the need for exogenous gonadotrophins is reduced when aromatase inhibitors are administered in the early follicular phase. Aromatase inhibitors may therefore serve a similar purpose as CC in mild stimulation protocols (Verberg et al., 2009a).

In recent years mild or “mini” IVF has become successfully established in certain countries such as Japan where the “Kobe protocol” has attracted much attention. This protocol uses oral contraceptive pill pre-treatment, extended daily clomiphene citrate dosing at 50 mg until triggering of final oocyte maturation with a GnRH agonist, and a daily dose of 75–150 units of FSH from cycle day 4 to 7. In recent randomized controlled trial comparing this protocol to the long protocol lower cumulative live birth rates were observed (49% vs. 63%) but OHSS was eliminated (Zhang et al., 2016).

Mild Stimulation in 2018

The case for mild approaches is attractive and it has gained a number of proponents. However, while the last 10 years has seen a move away from high dose long protocol regimens, adoption of a true mild treatment regimens into routine clinical practice has been slow. In part this reflects the deeply held view that fewer oocytes meant fewer pregnancies, and a caution in adopting a new paradigm for IVF treatment. While some later studies have questioned the concept of an optimal number of oocytes above which outcomes deteriorate, the notion that within the cohort of oocytes available for stimulation, only a few can generate viable embryos, and these can be obtained through milder stimulation has recently been reinforced (Arce et al., 2014). Some 10 years after the publication of the studies showing the potential of the mild approach, these debates continued. However, the underlying message has influenced the field and led to an overall reduction in the doses of FSH being used, and the duration of ovarian stimulation. The new “standard” approach to IVF is remarkably similar to the “mild approach” first advocated by Edwards, Fauser, and others. In 2018, mild stimulation has established its place as an attractive option for those wishing IVF treatment with a good chance of conceiving a singleton pregnancy within a realistic time frame while avoiding the burden, intensity, and costs of conventional approaches (Fauser, 2017).

Given the potential advantages of milder stimulation, it is not surprising that the idea of taking this to its logical conclusion and that “natural” cycle IVF, the approach which finally led to the birth of the first IVF baby, enjoyed renewed interest.

Natural Cycle IVF

This minimalistic approach relies on endogenous FSH to stimulate monofollicular development, and triggering of final oocyte maturation by either a spontaneous LH surge or the administration of hCG. Early approaches relying on the former required intensive cycle monitoring which placed a considerable burden on both patients and the clinic. The first large reported series also

highlighted the low efficiency of this approach. Of 162 treatment cycles, only 89 (55%) reached embryo transfer and only 9 (5.6% per started cycle) resulted in live births (Zayed et al., 1997).

A response to these disappointing outcomes, as well as the logistic challenges posed by cycle monitoring in this way was to propose that final oocyte maturation be triggered by giving an hCG injection to mimic a timed LH surge. A subsequent extensive review which analyzed the efficiency of ncIVF treatment in 20 studies published between 1989 and 2001 involving 1800 cycles showed that successful oocyte recovery rate varied greatly between studies (30%–96%) (Pelinck et al., 2002).

A retrospective review comparing outcomes after spontaneous LH surge or with the use of hCG injection suggested a modest margin of benefit after the former. In the LH group (534 cycles), eggs were collected in 81% of cycles whereas in the hCG group (241 cycles) this was 76% (Lenton, 2007). Moreover, a randomized clinical trial in intrauterine insemination treatment showed that ongoing pregnancy rates were significantly higher (23% vs. 11%) in spontaneously versus hCG-triggered cycles (Kyrou et al., 2012).

These possible differences need to be weighed against the inconvenience of twice daily LH monitoring and most clinics prefer hCG triggering because it permits the timing of oocyte retrievals and is convenient both for the patients and the clinic's staff. However, the risk of premature ovulation remains a concern and this has led to the development of "modified" natural cycles. They still rely on endogenous FSH to stimulate the growth of a single follicle, but like mild stimulation regimens, employ GnRH antagonists to prevent a premature LH surge, thus diminishing the risk of premature ovulation and permitting the triggering by exogenous hCG at a convenient time, thus greatly simplifying oocyte retrieval scheduling. In a pilot study in which GnRH antagonists were administered daily from when the leading follicle reached 12–14 mm and concomitantly daily doses of 150 IU hMG were given to maintain follicular stimulation (Rongieres-Bertrand et al., 1999). Of 44 cycles in <37-year-old patients, 91% resulted in oocyte retrievals, 50% in embryo transfers, and there were 5 (11.4%) ongoing pregnancies. These results were considered encouraging enough for this new protocol to become the treatment of choice for many centers offering "natural" cycle IVF.

In a study comparing outcomes after modified ncIVF versus conventional IVF in 134 patients under 35 years of age, 56% of the ncIVF cycles led to embryo transfer 15% to clinical pregnancies, compared with 45% after conventional stimulation (Phillips et al., 2007). In older patients (between 35 and 38 years), the corresponding rates were much lower at 3.7% versus 34% respectively. The authors concluded that although with modified ncIVF, the cancellation rate is very high it might be offset by the fact that the mild treatment option is less hard on patients, could be repeated in each month, and costs less. The largest published series on modified ncIVF by Pelinck et al. (2007) reported the outcome of 1048 cycles on a cumulative basis in patients who were offered up to 9 treatment cycles. Per cycle ongoing pregnancy rates were 7.9% but reached 44.4% cumulatively.

Although to date no significant studies comparing the non-drug natural cycle with the GnRH antagonist-based "modified" natural cycle IVF protocol, the available data indicates that the overall cycle outcome is similar to protocols that only use exogenous hCG to trigger final oocyte maturation. This may be explained by the reported limited ability of GnRH antagonists to entirely prevent premature LH surges in the context of a non-stimulated cycles with relatively low steroid levels. Indeed it has been suggested that an increased GnRH antagonist dose might be necessary to completely prevent the occurrence of LH surges and given the relatively limited advantage offered, the cost effectiveness of this approach is debated (Reyftman et al., 2007). In a small study in eight volunteers treated with transdermal E2 with or without daily GnRH antagonist co-treatment (Messinis et al., 2010), GnRH antagonists were unable to block the occurrence of LH surge induced by supra-physiologic E2 levels. It was suggested that GnRH antagonists behave differently during ovarian stimulation and non-stimulated cycles with an additional role of other endocrine factors, such as the putative gonadotropin-surge attenuating factor (Messinis et al., 2010).

A systematic review of the efficacy of natural cycle IVF (Pelinck et al., 2002) summarized the findings of 20 studies comprising a total of 1800 initiated ncIVF cycles. This review included studies where HCG was the only drug used for induction of oocyte maturation and where it was possible to calculate ongoing pregnancy rates per started cycle from published data. This review concluded that only 45.5% of initiated cycles reached embryo transfer resulting in a 7.2% ongoing pregnancy rate per initiated cycle. However, there was a great variation among studies and embryo transfer and ongoing pregnancy rates per started cycle varied between 22%–80% and 0%–16%, respectively. The authors argued that further refinements such as the use of GnRH antagonists for controlling LH surges or NSAID to prevent premature ovulation might further increase the efficiency of ncIVF treatments, but the added value of these interventions remains to be demonstrated.

More recently, Roesner et al. (2014) reviewed the 5-year experience of their center in Germany involving a natural cycle IVF approach in which only hCG was administered to trigger final oocyte maturation, and compared it with the reported outcomes of 28 ncIVF studies published between 1995 and 2012. Clinical pregnancy rates per embryo transfer varied widely between 10% and 56%; figures consistent with those derived by Pelinck et al. (10%–50%). During the 10-year period that separates the publication of these two literature reviews, there was no apparent improvement in the overall efficiency of natural cycle IVF treatments.

The overall low per cycle efficiency of natural cycle IVF approach can be ameliorated by repeating successive treatment attempts. A number of studies have reported cumulative success rates following (modified) natural cycle approach. The earlier UK study reported the outcome 181 cycles performed in 52 infertile women (Nargund et al., 2001). Although per cycle live birth rate was only 8.8%, by performing four treatment attempts a cumulative live births rate of 32% was reportedly achieved. A large study from Groningen reported the cumulative outcome of 1048 modified natural cycle IVF (mncIVF) cycles performed in 256 patients (Pelinck et al., 2007). The participants, all under 37 years of age, were offered a maximum of 9 cycles, although on average 4.1 attempts were made. Ongoing pregnancy rates were 7.9% per cycle were reported but cumulative rates reached 44.4%. These data provided further support to the notion that modified ncIVF may represent a valuable treatment alternative to conventional ovarian stimulation when outcomes are considered over a course of treatment rather than per cycle.

Table 1 Challenges of natural cycle IVF

Challenges	Possible solutions	Advantages/drawbacks
Uncontrolled LH surge	Flexible scheduling GnRH antagonists Low-dose clomiphene	Very challenging Additional cost, inefficient? Endometrial effect?
Premature ovulation	NSAIDs	Cheap, efficient
Empty follicle	Follicular flushing	Time consuming
Immature oocyte	In vitro maturation	Low efficiency
Mandatory single embryo transfer	Optimized ultrasound-guided embryo transfer technique	Requires training
Low per cycle efficiency	Repeated cycles Patient selection	Risk of drop-out Limits patients access

Adapted from Bodri, D. (2017). Natural cycle IVF with the spontaneous LH surge. In: Chian, R. C. et al. (eds.) *Development of in vitro maturation for human oocytes*. Springer International Publishing AG.

A recently published 3-year cohort study also reported cumulative success from a program based uniquely on ncIVF and minimal ovarian stimulation (Bodri et al., 2014). Although this cohort was a mixture of different mild treatment approaches, natural cycle IVF still represented 57% of all treatment attempts. Crude cumulative live birth rates were favorable in young patients (65% and 60% in <35 and <38-year-old patients, respectively), still acceptable at intermediate age (39% for patients between 38 and 40 years of age) and declined gradually in >40-year-old infertile patients. Moreover, a plateau was also detected after approximately four to six treatment cycles.

A recent registry-based study from the United States yielded further insights into the efficiency of ncIVF treatment in different age groups. The review presented data on all 795 unstimulated IVF cycles that were registered in the SART (Society for Assisted Reproductive Technologies) database during 2006 and 2007 (Gordon et al., 2013). However, the average number of unstimulated cycles per reporting center was <10 per year and hence only represented a tiny fraction (1.5%) of all treatment cycles performed at each center. Limited experience and a selected (poor prognosis) population may have adversely affected reported outcomes. Indeed many clinics will offer natural cycle IVF primarily to poor prognosis, older patients with diminished ovarian reserve and poor egg quality for whom stimulated IVF offers little added value.

When offered to good prognosis patients outcomes can be better. The authors of the SART analysis reported embryo transfer and live birth rates per started cycle in <35 years patients of 54% and 15%, respectively, declining to 42% and 9% in 38–40-year-old patients and further in patients >40-year old. However, compared to stimulated IVF implantation rates per embryo were higher overall, suggesting some benefits from the avoiding the supraphysiological estradiol levels associated with ovarian stimulation. Taken together, these data suggest that ncIVF should be considered in younger patients (<38 years) rather than limiting it to older patients in whom all other treatment options have failed.

The above findings derived from the US registry were corroborated by a recent retrospective analysis of 469 natural cycle IVF cycles performed in 164 poor responding patients (Polyzos et al., 2012). In comparison to stimulated cycles, the authors found embryo transfer and live birth rates to be significantly reduced, concluding that natural cycle IVF does not represent any substantial benefit to this group.

A number of challenges relating to natural cycle continue to be encountered and these are summarized in Table 1.

Conclusions

The origins of mild and natural cycle IVF go back to the very early days of clinical IVF. However, it has required an increase in the efficiency of assisted conception technologies, together with an appreciation of the risks, costs, and burden of conventional stimulation protocols to reawaken interest in this lighter approach to treatment. While they continue to represent a relatively small proportion of IVF cycles worldwide, the advantages are widely recognized and have led to a reconsideration of standard clinical practices, with an increasing trend to using lower doses of FSH and stimulation regimens designed to limit the risk of complications of IVF. A number of patients remain attracted to these milder approaches for the reasons outlined in this article; a less invasive, less costly more natural treatment that reduces the disruptive side effects of ovarian stimulation with exogenous gonadotropins while still offering for many a reasonable chance of receiving a high quality embryo, and an acceptable chance of conceiving a health pregnancy over a number of cycles (Nargund et al., 2017).

Introduction

Controlled ovarian stimulation (COS) is crucial in assisted reproductive technologies (ART). The aim of COS is to promote the simultaneous maturation of multiple follicles in order to collect the adequate number of oocytes that can be subsequently used for in vitro fertilization. This goal is obtained by the use of gonadotropin medications, which induce multiple follicular growth. During COS, medications that suppress pituitary function, such as gonadotropin releasing hormone (GnRH) analogues, are prescribed in order to prevent an unwarranted ovulation before the scheduled oocytes retrieval. The ovulation of the recruited follicles is triggered only at the end of the ovarian stimulation with specific drugs with luteinizing hormone (LH) activity. In **Fig. 1** is illustrated the history of gonadotropin formulations.

Fig. 1 The history of gonadotropin formulations.

In summary, COS requests the use of three classes of drugs:

- Follicle-stimulating drugs (recombinant or menopausal gonadotropins);
- Modulating-ovulation drugs (GnRH agonist and GnRH antagonist);
- Ovulation-inductor drugs (hCG and GnRH agonist);

Table 1 reported the pharmacological properties of the most common products available in the market.

Medications for Controlled Ovarian Stimulation

Follicle-Stimulating Drugs

Follicle-stimulating gonadotropins can be divided in:

- Recombinant gonadotropins, synthesized through genetic engineering techniques (recombinant DNA technique): follitropin- α , follitropin- β , corifollitropin- α , lutropin- α .
- Menopausal gonadotropins, extracted from menopausal women's urines, containing (follicle stimulating hormone) FSH and LH in different proportions (menotropin) or containing only FSH (urofollitropin).

Follicle stimulating gonadotropins induce follicle growth by binding to specific membrane receptors, localized in both theca and granulosa cells.

Menotropin

Menotropin is extracted from the urine of postmenopausal women (Lunenfeld, 2004). Early preparations contained varying levels of FSH, LH, and human chorionic gonadotropin (hCG). Currently, new purification techniques resulted in FSH and LH activities standardized at 75 IU for each type of gonadotropin (ASRM, 2008). Human menopausal gonadotropin (hMG) have both FSH and LH activity, but the latter is primarily derived from the hCG component in postmenopausal urine, which is concentrated during purification (Lunenfeld, 2004). Occasionally, hCG is added to induce the desired level of LH-like biological activity (Lunenfeld, 2004). Currently, hMG are commercially available at FSH:LH ratio of 1:1.

FSH is fundamental for follicular recruitment in the first stages of folliculogenesis, while LH is important for ovarian steroidogenesis and is involved in physiological events that promote the growth of an appropriate preovulatory follicle in the last stages of folliculogenesis.

In view of that, menotropin, having a double activity (FSH and LH), induces the growth and the development of ovarian follicles as well as the gonadic steroids in women with primitive ovarian deficiency. After an intramuscular or subcutaneous administration, the menotropin is excreted mainly by the kidney.

Furthermore, according with LH action in steroidogenesis strengthening, estradiol levels associated with menotropin treatment are higher than those associated with the one based on recombinant FSH (r-hFSH) in IVF cycles. This must be considered during stimulation. It is available in the pharmaceutical form of solution or powder with dosages of: 75 IU, 600 IU and 1200 IU.

Table 1 Pharmacological properties of the most common products available in the market

Gonadotropin preparation	FSH activity	LH activity	Route of administration	Route of elimination	Half-life
Menopausal gonadotropin	75 or 600 or 1200 IU	75 or 150 IU	i.m. or s.c.	Via kidneys	30 h (s.c.) 27 h (i.m.)
Urofollitropin	75 or 150 or 225 or 300 IU	Negligible	i.m.	Via liver and kidneys	35–40 h
Follitropin α	75 or 150 or 450 or 900 or 1050 IU	0	s.c.	Via liver and kidneys	24 h
Follitropin β	100 or 150 or 200 or 900 IU	0	i.m. or s.c.	Via liver and kidneys	26.9–43.9 h (dose dependent)
Corifollitropin α	100–150 μ g	0	s.c.	Via kidneys	65–70 h
Lutropin α	0	75 IU	s.c.	< 5% of dose excreted renally as unchanged drug	10–12 h
Urinary hCG	0	1000 or 2000 or 5.000 or 10.000 IU	i.m.-s.c.	Via liver and kidneys	29–36 h
Recombinant hCG	0	250 μ g	s.c.	$\cong$ 10% of dose excreted renally as unchanged drug	29–36 h

s.c.: subcutaneous; i.m.: intramuscular; h: hour; IU: international unit; μ g: microgram

Due to individual variability of ovarian response to the exogenous gonadotropins treatment, it is not possible to define a uniform dosing schedule. The recommended initial dose is usually 150–225 IU per day for at least the first 5 days, but it could be modified during the stimulation on the base of estradiol levels or follicles growth. Generally, the maximum dose should not exceed 450 IU per day and for no more than 20 days.

Urofollitropin

The urofollitropin belongs to the highly-purified gonadotropins family. It is also extracted by postmenopausal women's urines, but unlike hMG it is mainly characterized by the FSH action. This highly purified formulation contains less than 0.1 IU of LH and 5% of urinary proteins and could be administrated subcutaneously.

Urofollitropins are indicated for ovulation induction in women affected by chronic anovulation, although they could be also used for controlled ovarian stimulation treatments in women who underwent in vitro fertilization.

Posology depends on patient's needs and should be evaluated on a case-by-case basis. For example, in women affected by chronic anovulation, it is recommended a dosage between 75 and 150 IU per day. Among the women candidates for in vitro fertilization techniques, the initial dose ranges from 150 to 225 IU per day. The maximum recommended dose should not exceed 450 IU per day.

The preparations currently available can be used in subcutaneous or intramuscular form, in solution or powder form at dosages of 75 IU, 150 IU, 225 IU, 300 IU.

Follitropin alpha

The Follitropin α is a recombinant molecule of natural FSH (follicle-stimulating hormone) synthesized by Chinese hamster ovary (CHO) cell line into which has been inoculated a gene able to synthesize human FSH. In detail, FSH α and β subunits are incorporated into DNA of host CHO cells using specific plasmid vectors containing FSH gene and bacterial segments (Lunenfeld, 2004). After subcutaneous injection, the absolute bioavailability is about 70%. The initial and terminal half-lives after the administration of 150 IU recombinant FSH are 2 h and 24 h respectively (Leao and Esteves, 2014). Delivery systems include pen-shaped administration devices or lyophilized powder formulation (ASRM, 2008).

In patients undergoing COS for ART, the commonly used regimen requires the administration of 100–225 IU per day and could be progressively calibrated according to patient's response.

Follitropin beta

The Follitropin β is synthesized, like the Follitropin α , through the DNA recombinant technique from a Chinese hamster's line of ovarian cells, edited with human FSH genetic subunits.

Purification process and glycosylation are different in Follitropin α and Follitropin β formulation (Olijve et al., 1996). Nonetheless, these molecular differences do not have significant impact on clinical practice (ASRM, 2008).

In the same way as Follitropin α , Follitropin β can be used to induce follicular growth in case of chronic anovulation and could be adopted in controlled ovarian stimulation before in vitro fertilization.

Follitropin β is administrated subcutaneously and its peak level is reached within 12 h from administration. The absolute bioavailability is about 77% and an elimination half-life of 26.9–43.9 h (Table 1).

Follitropin β is available in liquid (pens/cartridges devices) or in lyophilized powder formulation (ASRM, 2008).

In controlled ovarian stimulation protocols, an initial dose of 100–225 IU per day is recommended. Afterward, any dosage modification is required on the basis of individual ovarian response.

Corifollitropin alpha

Corifollitropin α is a molecular hybrid obtained by the fusion of human Chorionic Gonadotropin β subunit carboxyl-terminal peptide with human FSH β chain (Balen et al., 2004). The addition of carboxyl-terminal peptide, which has 4 connected oligosaccharidic chains, provides a slower absorption and a longer plasmatic half-life while maintaining the same pharmacodynamic profile (Boime and Ben-Menahem, 1999).

The molecule acts exclusively on FSH receptors, missing of a LH-like activity. The plasmatic peak is reached 44 h after the administration and the resulting absolute bioavailability equals 58%.

The Corifollitropin α has an elimination half-life of 65 h and has a primarily renal clearance (Verbost et al., 2011).

The pharmacokinetic profile after a single injection is characterized by a higher stimulant FSH activity in the first 2 days of stimulation, followed by a gradual reduction of activity.

To date, the Corifollitropin α is available at the dosages of either 100 or 150 micrograms. The latter is suggested for women weighing more than 60 Kg or older than 36 years (Devroey et al., 2009, 2004).

Because of a higher half-life, one single subcutaneous injection of the recommended dose can replace the first 7 daily injections of r-hFSH. The stimulation usually starts on the 2nd–3rd day of menstrual cycle with a single subcutaneous injection. Afterwards, the stimulation can be further continued through the addition of exogenous FSH either in recombinant or in menopausal form at variable doses, according to ovarian response.

The main issue concerning the use of Corifollitropin α is the impossibility to adapt dosage during the ovarian stimulation in the first 7 days of stimulation (Patil, 2014). Moreover, in patients with a high risk of developing an excessive response to the ovarian

stimulation, its use should be avoided (Patil, 2014). On the other hand, in patients with normal response to the treatment, the Corifollitropin α can be a valid and a better patient-friendly alternative to the conventional treatments.

Lutropin α

Lutropin α is a recombinant human luteinizing hormone (r-hLH) glycoprotein, composed by two subunits α e β linked by non-covalent bonds.

According to the “two cells/two gonadotropins” hypothesis, LH and FSH are both essential for folliculogenesis. LH binds, a receptor shared with the hCG in both theca and granulosa cells.

The supplementation of LH could be of benefit in specific subgroups of women undergoing ART (Alviggi et al., 2011). For instance, recombinant LH in association with FSH is recommended for the induction of follicular growth in adult women with hypogonadotropin hypogonadism (Dhillon and Keating, 2008).

The role of LH is not limited to the support of androgenic production, but it also seems important in the biological functions carried out by granulosa. Data show how LH can improve the quota of cAMP in late proliferative phase in this compartment. Hence, the hypothesis of an expression of LH receptors in the granulosa (Jeppesen et al., 2012).

A recent meta-analysis pointed out how, in women in advanced reproductive age, the supplementation with recombinant LH can result in a significant improvement of implantation and pregnancy rate (Hill et al., 2012).

Moreover, LH administration increases the number of recovered oocytes and IVF outcome, compared with the sole increase of FSH dosage in women with a stagnation in follicular growth during COS (Ferraretti et al., 2004; De Placido et al., 2005). These women, identified as *hypo-responders*, represent approximately the 10%–12% of normogonadotropic women who underwent IVF (Alviggi et al., 2013).

After subcutaneous administration, the absolute bioavailability of Lutropin α is about 60% and has a terminal half-life of about 10–12 h, compared to 35–40 h of menopausal gonadotropin formation (Leao and Esteves, 2014). Clearance is about 2 L/h and less than 5% is eliminated with urines.

Recombinant LH has been used for clinical use since 1993, in vials designed to deliver 75 IU. A new combination of recombinant FSH plus recombinant LH was introduced in 2007 at 2:1 ratio. This new formulation shows similar bioequivalence of follitropin α and lutropin α administrated alone (Picard et al., 2008).

Ovulation Modulating Drugs

The administration of gonadotropins during COS is associated to an increased risk of spontaneous early LH surge that could result in an unwarranted ovulation. The use of GnRH analogues suppresses hypothalamic-pituitary-gonadal axis and prevents the early LH surge, providing a longer duration and higher power compared to the endogenous GnRH. There are two types of gonadotropin releasing hormones analogues adopted during in vitro fertilization: GnRH agonist and GnRH antagonist.

GnRH agonist

The use of GnRH agonist has been considered a milestone in preventing LH surge until the beginning of 2000. The GnRH agonist initially binds to its pituitary receptors, determining a transient increase of gonadotropins secretion, called *flare-up* effect. Subsequently, the continuous stimulation of pituitary receptors provokes a *down regulation* that results in the suppression of gonadotropins production.

GnRH antagonists

GnRH antagonists were launched at the beginning of the century. Compared to GnRH agonists, they cause an immediate block of gonadotropins release through a competitive antagonism for the receptor site. Requiring shorter time for pituitary suppression, they could be administrated in the late follicular phase (stimulation day 7–8) or when the size of leading follicles is around 13–14 mm. GnRH antagonists are administrated in a single (3 mg depot-formulation) or in multiple dose regimen (0.25 microgram daily).

Ovulation-Inductor Drugs

Human chorionic gonadotropin (hCG)

hCG is an hormone produced by the placenta during the pregnancy. It is characterized by a similar structure to LH and it is used to induce follicles maturation and to trigger ovulation, which occurs approximately 36 h after administration.

Currently, urinary preparations are the most used at dosage of 10,000 UI or 5,000 IU and are administrated intramuscularly when at least one follicle exceeds the dimensions of 17–18 mm.

Recombinant forms of hCG are also available and, likewise other recombinant gonadotropin, derive from genetically form Chinese hamster's line of ovarian cells though recombinant technologies. Comparing with urinary form, recombinant hCG is characterized by higher purity that makes this medication suitable for subcutaneous administration (Leao and Esteves, 2014). Pharmacogenetic profiles do not differ from urinary formulations with linearity over a dosage range of 500 IU and 20,000 IU and half-life of 30 h (Trinchard-Lugan et al., 2002).

In case of in vitro fertilization, the time of hCG administration is crucial; as a matter of fact the oocyte pick up should be performed about 36 h after the administration.

According to the last meta-analysis, there is no difference between recombinant or urinary forms in terms of ongoing pregnancy rates or risk of ovarian hyperstimulation (Youssef et al., 2016).

GnRH analogues

This new approach was proposed to reduce the risk of ovarian hyper stimulation syndrome (OHSS) onset during ovarian stimulation. OHSS is a potential life-threatening complication that can occur following the administration of hCG at the time of ovulation induction.

In the protocols of ovarian stimulation with GnRH antagonists, the analog is able to unseat the antagonist molecule on the pituitary, inducing a FSH and LH increase and finally the follicular maturation. When the diameter of a follicle is 17–18 mm, ovulation can be induced using a dosage of 0.2 mg subcutaneously.

Despite a decrease of OHSS risk, a reduction of pregnancy rate has been observed as a consequence of the lack of hCG activity during the luteal phase. Therefore, various strategies have been proposed to increase pregnancy rates in the protocols that use GnRH analogues as triggering:

- Administration of low doses of hCG (1500 UI) starting from the day of oocyte *pick-up*.
- Support of luteal phase with high doses of estradiol and progesterone in variable doses and formulations.
- Freezing of oocytes and embryos collected that could be used in a different cycle.

Stimulation Protocols

For many years, the most common used GnRH analogues for pituitary suppression in COS were GnRH agonist medications. More recently, new regimens based on GnRH antagonist have been introduced. Compared with GnRH agonist, these drugs induce an immediate pituitary suppression and are associated with shorter duration of the treatment, lower amount of gonadotropin required and lower risk of ovarian hyperstimulation syndrome (OHSS). Nonetheless, pregnancy and live-birth rate are comparable between GnRH agonist and GnRH antagonist regimen (Al-Inany et al., 2016).

Mild Protocol

The “mild” stimulation strategy has been proposed as an alternative to the standard stimulation protocol, in which a relevant amount of exogenous gonadotropins is spent. This strategy follows the theory that the stimulation with the minimum concentrations of drugs could promote the recruitment of good quality follicles at the expense of a reduced amount. Mild protocol offers several advantages such as a patient-friendly approach and a reduced risk of ovarian hyperstimulation consequences. Nonetheless, this strategy is usually criticized considering that the retrieval of less oocytes may impair IVF success. It is usually carried out by a low dose of exogenous FSH (100–150 IU/day) from day 4 of a spontaneous menstrual cycle (Fauser et al., 2010; Casano et al., 2012).

Long Protocol

Long protocol is widely used in IVF, however, short protocols with antagonist medication are becoming more and more frequent. It is characterized by subcutaneous or intramuscular administration of GnRH agonist via depot or daily formulation, starting from the 21st–24th day of previous menstrual cycle (late luteal phase). Ovarian stimulation starts when pituitary suppression is confirmed by low estrogenic plasmatic levels and no ultrasound evidence of any anomalous ovarian cysts, which usually occurs after 14–15 day of treatment. GnRH agonist administration ends the day of ovulation triggering.

Ultralong Protocol

This protocol is roughly similar to the long one, except that GnRH agonist is administrated for two or more consecutive cycles preceding ovarian stimulation. It is recommended in patients with history of endometriosis and adenomyosis. As a matter of fact, a recent meta-analysis demonstrated that this strategy could offer a significant improvement in clinical pregnancy rates in such patients (Sallam et al., 2006).

Short and Ultra-Short Protocols

In short and ultra-short protocols the administration of agonists (0.1 mg/day) starts from day one or two of the menstrual cycle (in conjunction with the commencement of ovarian stimulation) to the day of ovulation induction (short protocol), or just for 3 days (ultra-short protocol) (Maheshwari et al., 2011). The aim is to encourage the initial phase of stimulation through massive release of endogenous FSH and LH (“flare-up” effect). Bearing in mind such characteristics, these protocols has been widely adopted in *poor responders* patients (LoutRADIS et al., 2008). However, in general IVF population, there is a moderate quality evidence that short/ultra-short protocols are associated with lower clinical pregnancy rates than long one (Siristatidis et al., 2015).

Antagonists Protocols

In this protocol pituitary suppression starts after the administration of gonadotropins in the final phase of ovarian stimulation. In the fixed protocol the antagonist is administered at a scheduled day of stimulation (5th–7th), while in the flexible one the antagonist starts on the basis of follicular growth (i.e., 13–14 mm) or estradiol levels. In *poor responders*, some authors report an increased compliance to treatment reduced gonadotropins doses consumption and duration (Loutradis et al., 2008). In *hyper-responders*, others have shown that this protocol reduces the risk of OHSS and cycle interruption (Youssef et al., 2016).

Cancer Patients Protocols

As a consequence of the better survival rates, the number of women who survived after cancer has progressively increased and the quality of life is gaining importance. In that sense, fertility preservation should be encouraged in women with interest in future pregnancies. Among fertility preservation strategies, both embryo and oocyte cryopreservation after COS are the most widespread. Nonetheless, it is very important to minimize estrogen levels that usually raise during conventional COS in patients suffering from estrogen-dependent cancer (i.e., breast cancer). With this purpose, the concomitant administration of aromatase inhibitors is able to limit estrogens levels without compromising the ovarian response to exogenous gonadotropins (Azim et al., 2008).

Individualized Controlled Ovarian Stimulation

Variability in the infertile women population excludes the possibility of a single approach towards controlled ovarian stimulation. As explained above, modern technology has led to the development of new drugs, treatment options and quantitative methods that allow an individualized approach to IVF.

The personalization of treatments requires a comprehensive evaluation of several important aspects. First of all, age remains the best predictive factor of gametes euploidy rate. As a matter of fact, it was estimated that the percentage of abnormal embryos/oocytes dramatically increases in women over 35 years old. Strategies to improve the number of vital and euploid embryos in those women represent the most intriguing challenge nowadays considering that more and more women seeking ART are in advanced age. On the other hand, ovarian reserve markers, namely, FSH, anti-Müllerian hormone and antral follicle count (AFC), are also considered the most accurate predictors of ovarian reserve and could be successfully used to guide controlled ovarian stimulation.

The AFC (*Antral follicle count*) consists in the count of antral follicles performed with a transvaginal ultrasound probe by the 5th day of the cycle. It provides a direct quantitative measure of ovarian response to COS and it is related with the number of oocytes retrieved. Although a standardized method has been proposed (Broekmans et al., 2010), the inter- and intra-operators variability still represents a relevant drawback of this procedure.

Anti-Müllerian hormone (AMH) is the main hormonal biomarker used to assess ovarian reserve. It is produced by preantral and small antral follicles and it reflects the number of primordial follicles that characterizes the gonadotropin-independent phase of folliculogenesis.

Given the importance of AFC and AMH in the evaluation of ovarian response, several *cut-off* values based on these two markers were proposed to predict the risk of poor or hyper response to COS (Alvigi et al., 2016a; La Marca and Sunkara, 2014; Choi et al., 2011). Finally, there is an emerging evidence in literature which suggests that the ovarian sensitivity to exogenous gonadotropins could be also influenced by specific genotype profiles. Indeed, some studies report that polymorphisms of FSH receptor and the β -chain of LH may affect the success of COS (Alvigi et al., 2013, 2015, 2016b). If these data will be confirmed, an individual pharmacogenomic approach may allow to calibrate COS on the basis of individual genotype characteristics.

Acknowledgment

The authors would like to acknowledge Gabriele Basile for the final linguistic revision of the manuscript.

Role of Agonists and Antagonists in COS

Introduction

Although the first baby born after in vitro fertilization (IVF) in 1978 was conceived in a non-stimulated cycle (Stephoe and Edwards, 1978), it was soon realized that pregnancy rates were disappointingly low following such an approach (Edwards et al., 1980). Thus, it seemed reasonable that an increase in the probability of pregnancy might result from an increase in the number of embryos transferred. For that purpose, it was necessary to induce multifollicular development that would allow the retrieval of multiple oocytes and the creation of multiple embryos. This could be achieved by stimulating the ovaries with the use of gonadotropins (Garcia et al., 1983; Trounson et al., 1981).

Gonadotropin use, however, was frequently associated with the occurrence of premature luteinizing hormone (LH) surge. This was accompanied by ovulation before oocyte retrieval leading to cycle cancellation in approximately one out of five women (Janssens et al., 2000; Loumaye, 1990).

To prevent a premature rise in LH, gonadotropin-releasing hormone (GnRH) analogues were introduced in ovarian stimulation (Fleming et al., 1982), following the revolutionary work of Schally (Schally et al., 1971); Guillemin (Ling et al., 1973).

GnRH Agonists

The mechanism of action of GnRH agonist involves its binding to the GnRH receptor in the pituitary. This will induce the release of follicle stimulating hormone (FSH) and LH (flare-up effect), increasing, at the same time, the number of GnRH receptors present (up-regulation). However, prolonged activation of GnRH receptors by GnRH agonist leads to desensitization and consequently to suppressed gonadotrophin secretion.

Through the 1980s, 1990s and until the early 2000s, a period known as the GnRH agonist era, downregulation in ovarian stimulation for IVF was exclusively accomplished with the use of GnRH agonists (Marcus and Ledger, 2001). The use of GnRH agonists for pituitary downregulation and inhibition of premature LH surge resulted in significant improvements in IVF cycles, including a decreased risk of cycle cancellation, retrieval of more oocytes and an increased availability of good quality embryos for transfer. Consequently, a higher probability of pregnancy compared to cycles with no suppression of premature LH surge was achieved (Hughes et al., 1992).

The most common protocols using GnRH agonist for suppressing premature LH surge are the “long protocol”, the “short protocol” and the “ultrashort protocol”. The long protocol involves administration of GnRH agonist for approximately 2 weeks before gonadotrophin administration is initiated. According to this protocol, GnRH agonist is administered either in the early follicular (day two of the cycle), or in the mid-luteal phase (usually day 21) of the preceding cycle. Follicular initiation of GnRH agonist in a long protocol, however, has been associated with a higher risk of functional ovarian cysts.

The short and ultrashort GnRH agonist protocols take advantage of the initial flare-up effect, occurring after administration of GnRH agonist on day two of the cycle. Duration of GnRH agonist administration last for 3 days in the ultrashort protocol and until triggering of final oocyte maturation by human chorionic gonadotrophin (hCG) administration in the short protocol (Ng and Trew, 2012).

Based on a recently published Cochrane review (Siristatidis et al., 2015), no significant difference was found between the long and the short protocol regarding live birth (OR 1.60, 95% CI: 0.85–3.03; 4 RCTs, $n = 295$ women) and ongoing pregnancy rate (OR 1.21, 95% CI: 0.82–1.78; 8 RCTs, $n = 681$ women). Similarly, no difference was observed between the long and the ultrashort protocol (OR 1.78, 95% CI 0.72–4.36; one RCT, $n = 150$ women) or between long luteal and long follicular phase GnRH agonist protocols (OR 1.89, 95% CI 0.87–4.10; one RCT, $n = 223$ women) in terms of live birth/ongoing pregnancy rate (Siristatidis et al., 2015).

GnRH Antagonists

Inhibition of premature LH surge by GnRH antagonist is achieved by a completely different mechanism compared to GnRH agonists. GnRH antagonists bind competitively to the GnRH receptors in the hypophysis. This competitive blockade of the receptors prevents endogenous GnRH stimulatory effects on the pituitary (Reissmann et al., 1995). Consequently, the secretion of gonadotrophins is decreased within hours after GnRH antagonist administration, while the occurrence of a flare up effect is avoided. Discontinuation of GnRH antagonists leads to immediate, rapid recovery of the pituitary-gonadal axis (Kenigsberg et al., 1984).

GnRH antagonist use, however, was initially associated with severe allergic reactions (Hahn et al., 1985) that inhibited their use in ovarian stimulation. Despite this, GnRH antagonistic molecules kept on developing and in the early 2000s, the third generation of GnRH antagonists that lacked histamine release problems was introduced in clinical practice (Duijkers et al., 1998; Mannaerts

Fig. 1 Meta-analysis of RCTs comparing fixed versus flexible GnRH antagonist protocols.

and Gordon, 2000). Two types of third generation GnRH antagonists have been developed: Ganirelix (Organon, Oss, Netherlands) (Rabinovici et al., 1992) and Cetrorelix (ASTA-Medica, Frankfurt/M, Germany) (Klingmuller et al., 1993).

GnRH antagonists can be administered according to a multiple-dose scheme (Diedrich et al., 1994), where the antagonist is administered daily from stimulation day 5 or 6 onwards. Based on dose-finding studies, the optimal dose for the daily-dose GnRH antagonist scheme is 0.25 mg for both Cetrorelix and Ganirelix (Albano et al., 1997; Tgd-fs, 1998). GnRH antagonist can be initiated in either a fixed (day 6 of stimulation) or in a flexible (using ultrasound and/or hormonal criteria) protocol. A meta-analysis of four RCTs (Escudero et al., 2004; Kolibianakis et al., 2011; Ludwig et al., 2002; Mochtar and Dutch Ganirelix Study, 2004) comparing fixed versus flexible GnRH antagonist administration did not show a significant difference in clinical pregnancy rate between the two protocols (OR: 0.85, 95% CI: 0.65 to 1.11) (Kolibianakis et al., 2012b) (Fig. 1).

GnRH Agonists Versus GnRH Antagonists

The advantages and disadvantages of GnRH agonist/antagonists in ovarian stimulation for IVF have been described extensively in the literature (Table 1). Based on data from the German Registry, GnRH antagonist usage increased with time from 14.1% in 2000 to 67.0% in 2015, replacing gradually GnRH agonists as the analogue of choice for suppressing premature LH rise (D.I.R., 2000–2015) (Fig. 2).

Although the advantages of GnRH antagonists as compared to GnRH agonists were evident since their introduction in clinical practice in the early 2000 (Table 1), this was met with a lot of skepticism mainly due to doubts regarding the efficacy for pregnancy achievement. However, with time, it was made clear that the probability of pregnancy was not dependant on the type of analogue used (Al-Inany et al., 2011; Kolibianakis et al., 2006).

The most recent meta-analysis by the Cochrane group, comparing GnRH agonists with GnRH antagonists including 45 RCTs (Al-Inany et al., 2011), suggested, in addition, that a significantly decreased incidence of ovarian hyperstimulation syndrome (OHSS) was present with GnRH antagonists as compared to GnRH agonists (OR: 0.43; 95% CI: 0.33 to 0.57) (Al-Inany et al., 2011).

In line with this meta-analysis, the largest comparative randomized trial between the two analogues published in 2016 (Toftager et al., 2016), including 1050 women < 40 years of age undergoing a first cycle of IVF/ICSI showed that live birth rate per randomized patient was similar between the two analogue protocols compared (GnRH antagonist: 22.8% versus GnRH agonist: 23.8%; difference: – 1.0; 95% CI: – 6.3 to + 4.3; $P = 0.70$), whereas the incidence of severe OHSS was significantly lower in the GnRH antagonist versus the GnRH agonist protocol (5.1% vs 8.9%; difference: – 3.8; 95% CI: – 7.1 to – 0.4; $P = 0.02$, respectively) (Toftager et al., 2016).

Even though the risk of developing severe OHSS is significantly decreased in GnRH-antagonist protocols when hCG is used for triggering final oocyte maturation (Al-Inany et al., 2006; Al-Inany et al., 2011; Toftager et al., 2016), severe OHSS can still occur, especially in high responder patients.

Table 1 Advantages and disadvantages of GnRH agonist and antagonist for COS (Ludwig et al., 2002; Al-Inany and Aboulghar, 2001, Kolibianakis et al., 2006)

GnRH analogue	Advantages	Disadvantages
GnRH agonists	1. Follicle cohort synchronization 2. Retrieval of more oocytes	1. Initial increase in the secretion of gonadotrophins (flare-up effect) 2. Lengthy downregulation period 3. Estrogen deficiency symptoms during the downregulation period 4. Ovarian cyst formation 5. OHSS occurrence following hCG administration.
GnRH antagonists	1. Immediate action within a few hours after GnRH antagonist administration 2. No flare-up effect 3. Rapid reversibility of antagonist action 4. No ovarian cyst formation 5. No hypo-estrogenic side effects 6. Shortened duration of ovarian stimulation 7. Elimination of OHSS occurrence (potential for avoiding hCG for triggering final oocyte maturation)	1. Less flexibility regarding cycle programming as compared with the long, but not with the short, GnRH agonist protocol 2. OHSS occurrence following hCG administration although significantly decreased compared to GnRH agonists.

LH, luteinizing hormone; OHSS, ovarian hyperstimulation syndrome; hCG, human chorionic gonadotropin.

**Fig. 2** Proportion of cycles performed with either GnRH agonists or antagonists. Based on data published by the D.I.R. (2000–2015).

The replacement of hCG by GnRH agonist for triggering final oocyte maturation, followed by freezing all embryos and deferring transfer in subsequent cycles, appears to be currently the safest approach regarding the occurrence of severe OHSS resulting in its elimination (Griesinger et al., 2007; Kolibianakis et al., 2012a). It has to be noted that the option of replacing hCG with GnRH agonist is not feasible in GnRH agonist cycles and represents the main advantage of GnRH antagonists over GnRH agonists considering patients' safety (Kolibianakis et al., 2012a).

In conclusion, GnRH antagonists have rendered IVF treatment more patient friendly, requiring less days of treatment compared to GnRH agonists with similar efficacy to GnRH agonists regarding the probability of live birth. In addition, elimination of OHSS occurrence by GnRH agonist triggering and freezing of all embryos, feasible only in GnRH antagonist cycles, has led to the exclusive use of this protocol in high responder patients such as women with polycystic ovarian syndrome (PCOS). Taking into account all the advantages of GnRH antagonists, there is probably no much doubt that GnRH antagonists are the obvious analogue of choice for a safe, effective and patient friendly stimulation, gradually leading the GnRH agonist era to an end.

Monitoring COS and HRT Cycles

Monitoring COS

The basic principle in ovarian stimulation for IVF (usually termed as superovulation or controlled ovarian stimulation-COS) is the retrieval of an adequate number of oocytes, in order to produce enough embryos and select the best of them to transfer in the uterine cavity, thus maximizing the probability of pregnancy. The stimulation of the ovaries is carried out through the exogenous administration of gonadotropins subcutaneously, although endogenous production of gonadotropins by the per os administration of clomiphene citrate or aromatase inhibitors is also possible. In modern assisted reproduction, the exogenous gonadotropins are mainly used for COS and it is clear that their efficacy is independent of their origin, since the live birth rates are comparable between urinary and recombinant gonadotropins ([van Wely et al., 2011](#)).

During the course of COS, it is mandatory to block the endogenous LH surge and the subsequent luteinization of the developing follicles. This LH surge is premature, namely it occurs when the sizes of the leading follicles are small, and is induced by the increasing levels of estradiol that is secreted from the stimulated follicles. For the blockade of the premature LH surge, the GnRH analogues are administered (agonists or antagonists) according to the respective protocols. Although both protocols are similar in terms of efficacy, the GnRH antagonist is safer than the agonist protocol, since it is related to lower ovarian hyper stimulation syndrome (OHSS) rate ([Al-Inany et al., 2016](#)).

The duration of the COS in the IVF/ICSI cycle is about 2 weeks and the monitoring is of paramount importance to obtain an adequate number of oocytes, avoiding poor or hyper ovarian responses. The quantification of the adequate number of retrieved oocytes is based on data from retrospective analyses of high numbers of IVF/ICSI cycles showing that the live birth rate increases with increasing number of retrieved oocytes up to 15 ([Sunkara et al., 2011](#)), while today it is generally accepted that poor and hyper responses are the retrieval of less than 4 and more than 15 or 20 oocytes, respectively ([Ferraretti et al., 2011](#), [Broer et al., 2013](#)). Furthermore, monitoring the COS will define the optimal time to give human chorionic gonadotrophin (HCG) for final oocyte maturation and finally avoid cycle cancellation which imposes significant psychological and financial burdens on patients.

In the long GnRH agonist protocol, the GnRH agonist daily injections usually start on day 21 of the previous cycle for pituitary down regulation and continues until the day of HCG administration. Once the pituitary down regulation is confirmed by low serum estradiol, progesterone and LH levels, usually after 12–14 days of GnRH agonist administration, the stimulation with daily gonadotropin injections starts. In the GnRH antagonist protocol, daily gonadotropin stimulation starts on the second day of the cycle and the daily injections of GnRH antagonist are added from day 5 onwards, until the day of HCG administration. However, today there are several variations of these protocols used in COS practice ([Tarlatzis et al., 2006](#)).

The first and most important step to approach the goal of adequate number of retrieved oocytes is the determination of the starting dose of gonadotropins. This is based on the blood levels of AMH, measured irrespectively of the day of the menstrual cycle, or the estimated antral follicle count (AFC) of both ovaries by transvaginal ultrasound in the early follicular phase before the treatment cycle. The AMH and AFC are the best biomarkers of ovarian reserves and predict more accurately the ovarian response to COS ([La Marca and Sunkara, 2014](#)). This AMH- or AFC-tailored individualization of COS is generally accepted today and the concept is that the higher the AMH levels or the AFC are, the lower the starting dose of gonadotropins should be given. Although some multifactorial models, taking into account the AMH, FSH, AFC and female age, have been proposed to select the starting dose of gonadotropins, these have not been fully validated as yet and in general, a starting dose of 200–225 IU, 300 IU, or 150 IU are used for expected normo-, poor or hyper-responders, respectively. The cutoff levels of AMH vary between studies and are also dependent on the assay used for its measurement. For example, the AMH levels measured with the manual DSL assay have been suggested to be 1 or 2.2, 5 or 15.6, and 15 or 28.6 ng/mL for expected poor, normal and hyper-responders, respectively. With the estimation of AMH levels by the modern automated assays, starting doses of Follitropin delta have been suggested to be 12 mg/d for AMH < 15 pmol/L and 0.10–0.19 mg/kg/d for patients with AMH ≥ 15 pmol/L ([Nyboe Andersen et al., 2017](#)). A multifactorial model, considering AMH levels, day 3 FSH levels, and female age, to tailor the starting dose of follitropin alpha in the first IVF cycle, has been shown to increase the proportion of patients with an optimal response, defined as the retrieval of 8–14 oocytes ([Allegre et al., 2017](#)).

Usually after 4 days of ovarian stimulation, the estradiol levels and/or the number of selected follicles (> 10 mm) are measured to quantify the ovarian response. If the response is adequate, the same dose of gonadotropins is maintained, while in cases of low or high response the dose is increased or decreased, respectively. The range of adequate ovarian response is not well defined and the cutoff level of estradiol suggesting a hyper-response is about 600 pg/mL. However, the cutoff levels studied as yet, are of limited prognostic value for the OHSS. Even the strategy of coasting, which means the withdrawal of gonadotropins administration while the GnRH analogue is given for less than 4 days, is an ineffective way to prevent OHSS, while a significantly lower yield of oocytes is obtained. On the other hand, the increase of FSH dose above 300 IU daily does not increase the number of retrieved oocytes in poor responders.

Fig. 1 Ultrasonographic measurement of developing follicles in COS.

In order to ensure safety and schedule the timing of HCG administration, ultrasound monitoring of the number and size of the developing follicles continues usually on a basis of alternate days, although even daily monitoring may be necessary. The diameter of each follicle is measured in two perpendicular planes and the average diameter is then calculated (**Fig. 1**).

The follicles grow at a rate of 2–3 mm per day and the average number of ultrasound scan monitoring is about two to three until the criteria for HCG administration are accomplished. Monitoring blood levels of estradiol together with ultrasound scanning is a usual practice, although there is no evidence to support that it improves pregnancy rate and decreases the OHSS rate compared to ultrasound monitoring alone ([Kwan et al., 2014](#)). Studies have shown that in the GnRH antagonist protocol, the number of follicles on the day of HCG administration have a higher predictive value for OHSS than the estradiol levels. If more than 18–19 follicles > 11 mm are measured in both ovaries on the day of HCG, the sensitivity and specificity for severe OHSS prediction are about 80% ([Griesinger et al., 2016](#)).

Endometrial thickness assessment at the time of transvaginal ultrasound scan monitoring has become part of standard monitoring during COS. The endometrial thickness is determined as the maximum distance between the two outer edges of the endometrial image on a longitudinal section of the uterus. Many studies have shown that an endometrial thickness below 8 mm on the HCG day is associated with lower pregnancy rates compared with thicker endometrium. Besides thickness, the sonographic pattern may be of clinical significance. During the COS, the increase in thickness of a three-layer pattern (**Fig. 2**) is due to estradiol levels increase, reflecting normal follicular dynamics, and the presence of this pattern on the day of HCG seems to be related to higher pregnancy rates in various studies.

Serum progesterone levels measurement may provide important information during monitoring of COS cycles. The premature rise of progesterone during the late follicular phase of the COS cycle may affect the endometrium and the window of implantation, resulting in asynchrony between the endometrium and the developing embryo. It is generally accepted that a progesterone level above 1.5 ng/mL on the day of HCG administration for the final oocyte maturation has a negative impact on pregnancy rates. For this reason, in cases with progesterone elevation it is advisable to cryopreserve embryos and transfer them in a future frozen-thawed embryos cycle ([Venetis et al., 2013](#)).

Human chorionic gonadotropin is used to trigger final oocyte maturation in IVF/ICSI cycles. HCG occupies the LH receptors and, when given exogenously, it actually mimics the function of the endogenous LH surge. Today it is clear that the effectiveness and safety of the recombinant HCG is comparable to the urinary HCG. Usually, HCG is given when three or more follicles reach the size of 17 mm. Prolongation of the follicular phase, i.e., triggering 2 days later after this criterion is met, in the GnRH antagonist protocol seems to be associated with lower ongoing pregnancy rates. The dose of urinary HCG is usually 5000–10,000 IU and the dose of recombinant HCG is 250 µg. The pregnancy rate is similar whether 5000 or 10,000 IU are given, while in high risk patients for OHSS doses as low as 3000 IU have been used without, however, enhanced safety. Doses below 2000 IU are ineffective to trigger final oocyte maturation.

Women with the polycystic ovary syndrome (PCOS) is a special group of IVF/ICSI patients, since the OHSS rate is about five times higher in these cases compared to patients with normal ovaries. Regarding the prediction of OHSS, such as in normal women, high AMH levels are related to increased risk for OHSS. PCOS women are hyper responders during COS and the monitoring

Fig. 2 Ultrasonographic appearance of the three-layer endometrium.

implemented is similar to that used in all women undergoing IVF/ICSI. Live-birth rates after COS for IVF/ICSI in women with PCOS seem to be comparable with those of women with other diagnoses, such as endometriosis, unexplained infertility or male factor infertility.

Many PCOS women have oligomenorrhea or amenorrhea and, therefore, the scheduling of COS with an induced menstruation is needed. This may be performed by the oral administration of combined contraceptives or progestins. However, the pregnancy rate after cycle scheduling with combined contraceptives may be lower compared to progestin induced scheduling. Obesity, depending on the population, may be prevalent in 40%–80% of PCOS patients, deteriorating the pregnancy rate and increasing the miscarriage rate. The GnRH antagonist is the protocol of choice, due to about 50% decrease in the risk of OHSS compared to the GnRH agonist protocol and comparable pregnancy rates. Moreover, it allows the induction of final oocytes maturation with GnRH agonist instead of HCG, thus eliminating practically the occurrence of OHSS (Tarlitzis et al., 2017).

Monitoring HRT Cycles

Frozen-thawed embryo transfer (FET) is an important part of IVF/ICSI treatment and involves the freezing of surplus embryos originating from a fresh cycle that may be transferred in the properly prepared endometrium of subsequent cycles, thus increasing the cumulative pregnancy rate after an oocyte retrieval. The modern practice of elective single embryo transfer with high availability of frozen embryos for subsequent FET cycles, results in low multiple birth rate and reduced overall costs of the IVF/ICSI treatment. With the advent of vitrification, the survival of frozen embryos and the pregnancy rates have been improved compared to the earlier slow freezing technique. This resulted in higher implementation of this technique for segmentation of IVF or “freeze-all” protocols that are used to prevent the occurrence of late onset OHSS due to pregnancy. Furthermore, the vitrification of embryos may be of paramount importance in cases of serum progesterone rise on the day of HCG administration that deteriorates the pregnancy rate of the fresh cycle.

The aim in FET cycles is the synchronization between the developmental stage of the embryo and the prepared endometrium, in order to maximize pregnancy rates. This may be performed with monitoring the natural cycle or with hormone replacement therapy (HRT) in an artificial cycle.

The natural cycle FET is feasible only in women with regular ovulatory menstrual cycles. In this case, the endometrium is prepared by the secretion of endogenous estradiol from the leading follicle in the follicular phase and the detection of the spontaneous LH surge with blood or urine measurements, which signifies the onset of the luteal phase. Specifically, when the mean diameter of the leading follicle is at least 14 mm, morning urinary LH is monitored, a method convenient but not accurate enough to determine the exact timing of ovulation. Daily blood measurements of LH provide more accurate information about the increase of serum LH levels and the detection of the onset of the endogenous LH surge. Usually, FET is scheduled 5 or 7 days after detecting the LH surge for Day-3 or Day-5 embryos, respectively, given a minimal endometrial thickness of about 7 mm. The advantage of natural cycle FET is that no medications are used but there are also significant disadvantages, such as accurate determination of serum LH levels needs the daily or even twice a day measurements, while the commercial kits for urine LH detection seem to have a significant risk of false-negative results.

A modification of the natural cycle is triggering with 5000 IU of HCG, instead of the endogenous LH surge, usually when the mean diameter of the leading follicle is ≥ 17 mm and minimal endometrial thickness of 7 mm, while FET is performed similarly

to the natural cycle, i.e., the day of HCG injection corresponds to the day of the LH surge onset (increase in LH levels). In natural cycle FET, with spontaneous LH surge, the luteal phase may or may not be supported. Luteal phase support may be beneficial in terms of pregnancy rates, and usually starts 3 or 5 days before embryo transfer by administering progesterone vaginally or intramuscularly (IM) until the 5th week of pregnancy. In natural cycle FET with HCG induction, luteal phase support with progesterone does not seem to be beneficial probably due to the luteotropic effect and the long half life of HCG.

The HRT or artificial cycle protocols include the administration of exogenous estrogen and progesterone, with or without co-treatment with GnRH agonists. It is obvious that the HRT cycle may be applied in ovulatory and anovulatory women and also in women with ovarian quiescence, such as donor oocyte recipients with premature ovarian failure. The preparation of the endometrium for FET may be identical whether the aim is a cycle with the patient's vitrified oocytes or a cycle with fresh or vitrified donor oocytes or embryo donation.

A common practice for endometrial preparation is the oral administration of estradiol since it is simple and well-tolerated. On cycle day 2 or 3, after a transvaginal ultrasound scan ensures that there are no ovarian cysts, oral estradiol valerate administration starts. The dose of estradiol pills increases gradually, 2 mg/day on days 1–4, 4 mg/day on days 5–8, and 6 mg/day from day 9 onward, although various dosing schemes may be applicable. After 10–12 days of estrogen administration, the endometrial thickness is determined with transvaginal ultrasound. Estradiol is given at the same dose until the endometrial thickness on ultrasound is about 8 mm, which is usually accomplished after 10–14 days of treatment, but if the endometrium fails to respond, the duration of treatment may be extended. It should be noted that after oral administration, estradiol is metabolized by the intestinal mucosa and liver (first-pass effect), while with the transdermal route more stable steady-state levels of estradiol are produced. In cases, when with oral administration of estradiol an appropriate endometrial thickness is not attained, then it may be beneficial to shift to the transdermal route in a next cycle. It is rare that both oral and transdermal routes fail to achieve adequate endometrial thickness, but in these cases the vaginal route of estradiol administration may be helpful (Paulson, 2011).

Once the target of an endometrial thickness of about 8 mm is met, progesterone is added, while estradiol is continued, for the number of days proportional to the stage of development of the embryo that will be transferred. The day that the ultrasound scan detects the appropriate endometrium, it is also important to check that no dominant follicle nor signs of ovulation exist, since in such cases the endogenous progesterone may impact on the endometrium inducing secretory changes and distorting its synchronization with the developmental stage of the transferred embryo. Regarding the optimal synchronization for maximizing embryo implantation, it seems to be day 3 or 4 of progesterone administration for day-3 embryos, and day 5 or 6 of progesterone treatment for day-5 embryos. Progesterone is administered either vaginally, subcutaneously or intramuscularly. With the IM route the highest serum levels are achieved, while with vaginal administration the endometrial tissue levels are highest. However, both routes are similarly effective in terms of success rate in FET cycles. Usually, natural micronized progesterone is given vaginally at a dose of 400 mg every 12 h (suppositories) or 90 mg daily (gel) and is continued until either a serum pregnancy test result is negative, or in case of success, until 12 weeks of pregnancy. Alternatively, natural progesterone-in oil may be given IM at the dose of 50 mg daily or natural progesterone in aqueous solution SC at the dose of 25 mg/day.

Gonadotropin suppression with GnRH agonists has also been used in FET cycles on the basis that, although estradiol treatment in the early follicular phase inhibits ovulation, the complete pituitary suppression may not be achieved and some follicular activity can still occur, with possible adverse effects on implantation. Usually, pituitary down-regulation starts with daily administration of a GnRH-agonist from the mid-luteal phase (day 21) of the menstrual cycle. On the first day of subsequent menstruation, the endometrial preparation with administration of estradiol is initiated as described above. However, it seems that pregnancy rates are similar whether the FET cycles are supplemented or not with GnRH agonists.

Many studies as yet have investigated which is the best method of endometrium preparation in FET and it seems that all appear to be equally effective regarding pregnancy rates (Groenewoud et al., 2013). Therefore, patients' preferences play an important role in the selection of the most appropriate strategy.

Oocyte Retrieval

Michael M Alper, Boston IVF, Waltham, MA, United States

© 2018 Elsevier Inc. All rights reserved.

History of Oocyte Retrieval

In the early research years of IVF, there were no techniques available to easily extract eggs from the ovaries. With the advent of laparoscopy in the 1970s, the ovaries became more easily accessible and, in fact, Steptoe and Edwards used laparoscopy to obtain eggs for the first successful IVF case in 1978. Laparoscopy involves the placement of a pencil-size instrument just below the umbilicus to visualize the pelvic organs. Despite the breakthrough with laparoscopy, the technique required intubated anesthesia and also carried significant risks such as bladder and bowel injury, amongst other complications. Laparoscopy essentially limited IVF to the hospital setting, which resulted in the process being somewhat complex.

The advent of diagnostic ultrasound in the mid-1980s led to major advances in oocyte retrieval. Initially, only abdominal ultrasound probes were available and the only way to reach the ovaries was to place a needle (protected by a bladder catheter) into the bladder via the urethra and then piercing the bladder to reach the follicles. Trans-vesicle follicular puncture under abdominal ultrasound-guidance was less involved than laparoscopy but carried risks of hematuria and urinary tract infection. The development of the vaginal ultrasound probe led to the modern techniques used today.

The Modern Technique of Oocyte Aspiration

The natural cycle typically produces a single follicle and the efficiency of IVF is limited with only one egg/follicle. Most IVF programs use daily gonadotropin (FSH) injections to induce multiple ovarian follicles to develop. After 10 or so days of stimulation, the ovaries have multiple follicles typically of various sizes. Most programs target at least 10–15 follicles to form. Also, most follicles that measure 16–18 mm on ultrasound examination have mature eggs within them. When an adequate number of such follicles are present, the hormone hCG (human chorionic gonadotropin) is typically administered to induce final egg maturation and the oocyte retrieval is scheduled 35 h later. The hCG injection is often referred to as the “trigger shot.” (Note that hCG is biologically similar to luteinizing hormone, the hormone that induces egg maturation and ultimately ovulation in a natural cycle).

Before vaginal surgery it is important to cleanse the vagina to reduce the likelihood of introducing bacteria into the pelvic cavity. Although bacteriostatic solutions are used to prepare the vagina in most gynaecologic surgeries, solutions that are potentially toxic to oocytes must be avoided in IVF surgeries. For this reason, most IVF practices simply use saline to irrigate the vagina before egg retrieval in an attempt to remove as much debris and bacteria as possible. Studies have demonstrated that even though this approach does not use an antiseptic *per se*, the technique is effective.

The vaginal ultrasound probe is draped in a sterile cover and introduced into the vagina. Since the ovaries are positioned just behind the vagina, they are typically easily seen with the vaginal ultrasound transducer. A needle guide on the vaginal probe is used to position and guide the needle to traverse the vaginal wall (see Fig. 1).

Manufacturers produce oocyte aspiration needles of various sizes; most use 16–17 gauge needles. The aspiration needle itself is attached to fine tubing that ends in the cap of a test tube. The test tube cap has another tube that is also connected to suction so that the fluid in the needles is suctioned and collected in the test-tube. Most often, the surgeon controls a foot peddle that turns the suction on and off as the follicles are entered and the needle removed.

Fig. 1 Egg retrieval procedure demonstrating vaginal ultrasound probe with needle guide and egg retrieval needle with tubing (leading to test tube for egg collection).

Upon reaching the ovary, each follicle is aspirated in sequence. The needle tip is aimed at the center part of the follicle and the follicle can be seen to collapse around the needle tip as suction is applied. The typical straw-color fluid from each follicle is collected in the test-tube to be analyzed by the laboratory technician who searches through the fluid to find the microscopic egg. The technician looks through all the fluid collected and provides a running count of the number of oocytes retrieved.

Special Considerations

There are several issues that should be considered to optimize egg collection. The suction pressure must be correct. If the suction pressure is too low, then the flow of fluid will be reduced and leakage around the needle may occur and the follicle potentially lost. If the pressure is too high, then the rapid flow of fluid could damage the oocyte complex. It appears that a pressure of 140 mm seems best. Also, the eggs must be kept at a constant temperature as they wait to be discovered in the follicular fluid; the test tubes should sit in a warmer while waiting to be analyzed.

Also, it is important to minimize the number of times that the vaginal wall is pierced (to reduce infection and bleeding) so re-positioning the needle once past the vaginal wall is often used. Often just one puncture of the vaginal mucosa can result in aspiration of many follicles by simply angling the needle beyond the vaginal puncture site.

Some clinicians prefer to flush the follicles with media after initial aspiration in an attempt to improve the chances of retrieving the egg. Some needles are designed with an extra channel to allow for flushing. Studies have not demonstrated the value of flushing the follicles. Even patients with few follicles do not seem to have more eggs when the follicles are flushed (Mok-lin et al.). The disadvantage of flushing is that it adds considerable time to the procedure.

Various methods have been employed to make the egg retrieval comfortable for patients. Most programs use either conscious sedation or general anesthesia. Others have used local para-cervical blocks, acupuncture, and vaginal lidocaine. Centers using general anesthesia typically use propofol due to its short-acting characteristics and excellent amnesia. A Cochrane review evaluated 21 trials of pain control in women undergoing oocyte retrieval. The studies compared conscious sedation, general anesthesia, acupuncture, paracervical block, and patient controlled anesthesia. The conclusion was that all the various approaches worked to some extent. The use of more than one technique was associated with better pain relief. Of note is that the studies were not amenable to a meta-analysis due to design.

Risks and Complications

The risks of ultrasound-guided egg retrieval are finite and fortunately not that common. Bleeding is one of the most common complications of oocyte retrieval. The reason is that smaller blood vessels do not appear on ultrasound so it is not uncommon for a blood vessel between the vaginal wall and the ovary to be punctured inadvertently. Most of the time, if blood is seen emanating from the vagina it can be stopped with pressure. However, blood accumulating in the pelvic cavity is not typically noticed.

A study by Bodri and colleagues of 4052 retrievals revealed complications related to oocyte retrieval occurred in 17 patients (0.42%). The complications included intraabdominal bleeding ($n = 14$), severe pain ($n = 2$), and ovarian torsion ($n = 1$). Fourteen of the patients were hospitalized (0.35%) and six donors (0.15%) required surgical intervention. Pelvic infections, and injury to pelvic structures, nor anesthesia complications were not observed in this series.

A study by Ludwig and co-workers reviewed complication of 1058 egg retrievals. There were no complications from sedation or general anesthesia. Vaginal bleeding was observed in 2.8% of procedures, without any cases of intraabdominal bleeding. An injury of pelvic structures (a ureteral lesion) occurred in one case. No cases of pelvic infection occurred, but there was one case of unexplained fever was observed. Regarding pain, 3% of patients experienced severe to very severe pain after the egg retrieval and 2% of patients were still suffering from severe pain 2 days after the procedure. The pain level increased with the number of oocytes retrieved. About 0.7% of patients required hospitalization related to the egg retrieval.

Pelvic infection is another possible complication of egg retrieval. Despite a paucity of studies to demonstrate the value of prophylactic antibiotics, most IVF programs appear to use them in many or all cases. A study by Egbase and colleagues showed that prophylactic antibiotics administered routinely to women at the time of oocyte retrieval were associated with a reduction in positive microbiology cultures of embryo catheter tips 48 h later in 78% of patients. The implantation and clinical pregnancy rates were significantly lower in the women with positive microbial catheter-tip cultures. In a study of oocyte donors, 526 oocyte donors who received prophylactic antibiotics for oocyte retrieval were compared with a group of 625 patient controls that did not. Infection after retrieval was 0.4% in patients who did not receive prophylaxis compared to 0% in the group who received antibiotics.

Patients with endometriomas (especially if aspirated at the time of egg retrieval) may be at particularly high risk for infection. The reason is that the endometriotic fluid may act as a "culture" media for bacteria should they be introduced by the needle at the time of aspiration.

Other rare complications may occur. Urologic injury involving the ureter can be difficult to diagnose especially when masked by ovarian discomfort from stimulation. Fortunately, ureter and bladder injuries remain uncommon.

Pain management postoperatively is typically taken care of with acetaminophen or similar products. Patients having with difficulty increasing pain should be carefully evaluated for bleeding or ovarian accidents such as ovarian torsion. Patients with low pain tolerance or those with chronic pelvic pain should be evaluated carefully before surgery.

Summary

Vaginal oocyte retrieval is an important part of IVF. Current techniques use vaginal ultrasound guidance to pass a needle into the follicle. The needle is connected to a test-tube, which collects the eggs. Vaginal oocyte retrieval requires anesthesia and several methods have been promoted including general anesthesia and conscious sedation. The main complication from the procedure is bleeding. Prophylactic antibiotics may reduce the occurrence of infection.

Luteal Phase Support in IVF/ICSI- and Frozen Embryo Transfer-Cycles

Barbara Lawrenz and Human M Fatemi, IVI Middle East, Abu Dhabi, UAE

© 2018 Elsevier Inc. All rights reserved.

Introduction

The time between ovulation and onset of menses or, in case of conception, the establishment of a pregnancy is called “luteal phase”. After ovulation, the formation of the corpus luteum will occur under the influence of LH (luteinising hormone). The corpus luteum can be characterized as a timely limited endocrine organ, producing estradiol and up to 40 mg progesterone/day. Under the influence of progesterone the endometrium undergoes secretory transformation and also local vasodilatation and relaxation of the uterine muscle is promoted.

After conception the developing embryo will secrete human chorionic gonadotrophin (hCG). hCG produced by the embryo will maintain the secretory activity of the corpus luteum due to the structural similarity between hCG and LH and therefore by activating the same receptor. The corpus luteum will continue to produce progesterone until the shift of the progesterone production to the placenta has taken place at around 9 weeks of pregnancy.

Preconditions for a pregnancy are a functional embryo at blastocyst developmental stage, a receptive endometrium and synchrony between the embryo and the endometrium. Failure to achieve receptivity and synchrony results in infertility and this might be a limiting factor for success in IVF (In vitro-fertilization) – treatment.

Endometrial receptivity depends from the time of progesterone exposure after sufficient exposure to estrogen. The time frame in which the endometrium is receptive and able to support trophoblast–endometrial interactions is called “window of implantation” (WOI). The WOI is very limited in time and in a natural and idealized 28-day-cycle, it is thought to occur during a time around day 22–day 24. Previously it was assumed, that the WOI is more or less constant in time in all women. However lately it was shown, that the WOI can differ and displacement of the WOI might cause infertility, especially in the patients with repeated implantation failure.

Steroid Production of the Ovary in Natural and Stimulated Cycles

Estradiol and progesterone are essential for human reproduction in terms of providing the adequate endometrium for implantation. By administering estradiol and progesterone for endometrial preparation, pregnancies can be achieved with oocyte donation even in women without ovaries.

In a natural cycle, estradiol synthesis increases progressively from the dominant follicle and initiates LH (luteinising hormone) surge. Even before the LH-surge, a small increase in progesterone levels is seen, which reflects the increasing LH pulse amplitude and frequency leading up to the surge. A LH surge of 24–36 h is sufficient to initiate the resumption of oocyte meiosis, luteinization of granulosa cells, ovulation, and the initial phase of CL development. Progesterone and 17 α -hydroxyprogesterone (17 α -OHP) plasma concentrations increase rapidly after the LH surge or administration of human chorionic gonadotropin (hCG), indicating the beginning of granulosa and theca cell luteinization. The corpus luteum is producing up to 40 mg of progesterone per day and additional a significant amount of androgens and estradiol. This is unique to the corpus luteum of many primates, including humans (Devoto et al., 2009).

Progesterone biosynthesis occurs in two enzymatic steps: the conversion of cholesterol to pregnenolone (P5), a process which is catalyzed by the enzyme cytochrome P450_{scc} and further on its subsequent conversion to progesterone, through catalyzation by 3 β -hydroxy-steroid-dehydrogenase (3 β HSD). Under the influence of CYP 17, progesterone is further metabolized to androgens in the thecal cells. During early follicular phase, the enzymatic activity necessary to convert 17-OH-progesterone to androstenedione is absent or very low therefore concentrations of progesterone and estradiol rise with the increasing follicular diameter (Yding Andersen et al., 2011).

In a natural cycle with the development of a single dominant follicle, FSH-levels decline towards ovulation (Fleming and Jenkins, 2010). In IVF, multifollicular development is achieved by administration of daily high gonadotropin concentrations and in a normal/high responder, ovarian stimulation will result in a large number of growing follicles. Each follicle will contribute to the progesterone in the systemic circulation, therefore patients with more oocytes have high estradiol concentrations and significantly higher progesterone.

Without conception luteolysis will occur due to a lack of hCG support in the natural cycle and the corpus luteum will undergo a process of regression which leads to a decrease in progesterone production. In case of conception, the trophoblast will produce hCG, preventing the corpus luteum from regression and maintaining the progesterone production until placental progesterone production is adequate.

Influence of Progesterone on the Endometrium in Natural and Stimulated Cycles

Noyes et al. studied already in 1950 the different histological appearances of the endometrium, depending on the influence of estrogen or progesterone. Under the influence of progesterone, the epithelial glands and vasculature continue to grow and become

spiral. As the endometrial thickness remains relatively unchanged, this process results in a denser endometrium. By describing the histology for each specific day after ovulation, Noyes established in 1975 the classic endometrial dating paradigm that still serves as the gold standard for clinical evaluation of luteal function. An endometrial biopsy is considered to be “out of phase” in case it shows a difference of > 2 days between the histologic dating and the actual day after ovulation.

Comparison of endometrial steroid receptors and proliferation index between natural cycles and GnRH-agonist/hMG-stimulated cycles for IVF have revealed distinct alterations in endometrial maturation. On the day of oocyte pick-up procedure (OPU) in stimulated cycles, a more advanced secretory endometrial maturation combined with reduced estrogen receptors (ER) and PR and a low proliferation index in glands and stroma has been found (Bourgain et al., 2002).

It is assumed that the supraphysiological levels of estradiol and progesterone during stimulation lead to a reduced number of estradiol receptors (ER) and progesterone receptors (PR) and a low proliferation index in glands and stroma. Those endometrial alterations might affect the implantation. Patients with a progesterone level above 1.5 ng/mL on the day of hCG-administration have a different endometrial gene expression profile when compared to the gene expression pattern of patients below this threshold. These changes might explain the impairment of endometrial receptivity in the presence of elevated progesterone, reflected in the lower pregnancy rates reported in the literature (Bosch et al., 2003).

Endocrine Profile in IVF-Cycles After Oocyte Retrieval, Depending on the Type of Final Oocyte Maturation

Retrieval of mature oocytes after ovarian stimulation requires ovulation induction to mimic the LH-surge. Whereas in GnRH (gonadotropin-releasing-hormone)-agonist protocols final oocyte maturation has to be performed by the administration of hCG, in GnRH-antagonist-protocols the use of GnRH-agonist is also possible. Due to the specific way of action of hCG and GnRH-agonist, the endocrine profiles after OPU are different. In patients, triggered with either hCG alone or GnRH-agonist plus 1500 IU hCG, progesterone-levels on day 5 after oocyte retrieval procedure were highest and in patients after GnRH-agonist only and without any luteal phase support, were lowest. This difference is caused by the fact, that after hCG-application progesterone production of the theca cells is sustained to approximately at least 5 days due to the LH-activity and the half-life-time of hCG of > 24 h. Low levels of endogenous LH after GnRH-agonist trigger lead to low progesterone levels and can therefore cause severe luteal phase insufficiency (Fatemi et al., 2013).

Luteal Phase Support in Assisted Reproductive Techniques (ART)

A defective luteal phase occurs in almost all patients who undergo ovarian stimulation for ART and different theories have been discussed. Meanwhile the reason for the luteal phase insufficiency after ovarian stimulation is thought to be the multifollicular follicle growth during the follicular phase. The resulting supraphysiological luteal levels of progesterone and estradiol inhibit the LH secretion by the pituitary via negative feedback action (Fauser and Devroey., 2003).

To counterbalance luteal phase insufficiency after ovarian stimulation, luteal phase support (LPS) has to be applied. The possibilities are either direct substitution of progesterone via different routes of administration or stimulation of the remaining corpora lutea to sustain progesterone production.

Ways of Progesterone Administration

Oral Progesterone

Natural progesterone has been shown to be ineffective in inducing a sufficient secretory transformation after oral intake as it is rapidly metabolized. Synthetic progesterone derivatives are associated with side-effects, especially regarding the impact on the lipids and on the psyche, which will limit their use. To improve absorption and bioavailability progesterone can be micronized. However, even higher doses of micronized progesterone have failed to induce sufficient secretory transformation.

Progesterone i.m

Progesterone is rapidly absorbed after i.m. injection, therefore high progesterone plasma concentrations are reached after approximately 2 h and peak concentrations will be achieved after around 8 h. It seems that the i.m. site of the injection serves as a depot with progesterone accumulation in the fat tissue, resulting in sustained serum concentrations of progesterone (Nillius and Johansson, 1971). However the disadvantage of i.m. application of progesterone is the painful injection and the fact that daily injections are required to sustain sufficient progesterone concentrations. Additional swelling, redness and even sterile abscess formation are not uncommon side-effects and therefore lead to an increase of the physical treatment-burdens.

Vaginal Progesterone

After vaginal application, progesterone plasma concentrations reach maximal levels after approximately 3–8 h and then fall continuously over the next 8 h. Vaginal progesterone is cleared out of the circulation faster compared to i.m. progesterone, therefore higher

dosages of vaginal progesterone are needed to achieve luteal phase plasma levels. In most cases 300–600 mg of progesterone is administered daily, divided into two or three dosages, depending on the formula, like tablets, creams or suppositories. Vaginal absorption is influenced by the kind of formula preparation and is enhanced after previous oestrogenisation.

The serum levels measured after vaginal application are lower compared to i.m. application and sometimes even lower than measured in a natural cycle. Independently from the measured progesterone level, adequate secretory endometrial transformation is achieved after vaginal progesterone use.

Obviously, vaginally administered progesterone exerts a direct local effect on the endometrium before entering the systemic circulation. This is called “first uterine pass”-effect. Until now, the mechanism of the “first uterine pass”-effect is not fully understood and different ways of action are discussed: absorption of progesterone into the rich venous or lymphatic vaginal system and/or possibly countercurrent transfer between utero-vaginal lymph vessels or veins and arteries and direct drug diffusion through the tissues or even due to intraluminal transfer from the uterus to the vagina, similar to sperm transport. As the vaginal route is effective in providing sufficient luteal phase support and additional almost without any side-effects, it is nowadays the preferred route of progesterone administration. In case the increased discharge is not tolerated by the patient, rectal administration is also effective. Side-effects of rectal administration could be constipation and flatulence.

Human Chorionic Gondotropin for Luteal Phase Support

Due to the structural similarities of hCG and LH, hCG is able to activate the same receptor like LH. After hCG-application, no luteolysis will occur as the corpora lutea will be stimulated and progesterone production will be maintained. For a long time, the hCG-administration was the standard luteal phase support. The disadvantage is the possible development of ovarian hyperstimulation syndrome, especially in good responder patients (Ludwig and Diedrich, 2001).

Timing of Luteal Phase Support With Progesterone

Supraphysiological hormonal levels will suppress through the negative feedback of the hypothalamic-pituitary axis endogenous LH, which will lead finally to declining and low progesterone levels after OPU. To avoid a progesterone deficiency and therefore a negative impact on the endometrium, LPS has to be initiated before the endogenous progesterone levels are decreasing or low. On the other hand, preovulatory exposure of the endometrium to progesterone may have a negative impact on the endometrial receptivity.

Start of LPS before oocyte retrieval lead to a decreased likelihood of pregnancy, when compared to start on the day of oocyte retrieval. Initiation of progesterone on the evening of oocyte retrieval versus start on days 1–3 after oocyte retrieval did not lead to difference in clinical pregnancy rate. However, starting progesterone administration on day 6 will decrease the likelihood of pregnancy. Therefore, initiation of LPS between the evening of OPU and day 3 after OPU seems to be ideal (Connell et al., 2015).

Duration of Luteal Phase Support

In early pregnancy, lack of endogenous LH will be balanced by rapidly increasing amounts of hCG from the developing embryo. Progesterone production will shift from the corpora lutea towards the placenta between 7 and 9 weeks. Studies, which evaluated the duration of progesterone administration after a positive pregnancy test did not find any influence on the miscarriage rate and the delivery rate when progesterone application was continued or discontinued for 3 weeks after positive pregnancy test (Nyboe et al., 2002).

Luteal Support After GnRH-Administration for Final Oocyte Maturation

The use of GnRH-agonist for final oocyte maturation is meanwhile common in high responder patients as OHSS can almost completely be avoided. However, the first large randomized controlled trials after the introduction of GnRH-agonist for final oocyte maturation in GnRH-antagonist protocols reported a very poor reproductive outcome. It was assumed, that induced severe luteolysis, which develops due after the application of GnRH-agonist, cannot be counterbalanced using standard luteal phase support with “only” progesterone administration (Humaidan et al., 2005). To prevent luteolysis, administration of hCG or high doses of steroids is considered to be essential.

Luteolysis will occur when LH support is withdrawn for ≥ 3 days from the primate corpus luteum, hence it can be rescued if LH activity is reinitiated within 3 days corpus luteum function, so corpus luteum viability can be preserved without LH support for at least 72 h (Hutchison and Zeleznik, 1985).

Different treatment options have been described to maintain progesterone production from the corpora lutea and rescue the luteal phase. As GnRHa-induced luteolysis can be reverted by administration of hCG, one treatment concept is the application of low-doses of hCG during luteal phase. The rescue of the corpora lutea with hCG is dose dependent, and some studies suggested a hCG dose of ≥ 1500 IU, however also the application of low-dose HCG is effective in normalizing the reproductive outcome. Despite low dosages of hCG, OHSS can still occur in some patients.

OHSS can be almost completely avoided by the use of GnRH-agonist (200 mg of GnRH-agonist nasal spray twice daily; a total of 400 mg/d) for LPS after GnRH-agonist trigger without exogenous progesterone and midluteal progesterone levels of around 190 nmol/L (approximately 59.7 ng/mL) can be achieved (Bar-Hava et al., 2016).

Concept of Individualized Luteal Phase Support After Final Oocyte Maturation With GnRH-Agonist Trigger

Over the last years, ovarian stimulation for IVF-treatment is progressively individualized towards the patients' characteristics by the use of the ovarian reserve parameters anti-Muellerian-hormone (AMH) and ultrasound-based antral follicle count (AFC). However, until now LPS is performed uniformly in almost all patients.

Previously it was demonstrated, that GnRH-agonist trigger for final oocyte maturation would lead to severe luteolysis (Fatemi et al., 2013). However, luteolysis is not following the same pattern in all patients and some patients don't develop luteolysis at all. To avoid unnecessary administration of hCG with the consecutive risk of OHSS-development, a new concept of luteal coasting needs to be developed. Therefore, knowledge on predictive factors regarding the extend of the anticipated luteolysis with a possible subsequent development of luteal phase insufficiency without hCG-administration is needed. Additional randomized prospective trials have to evaluate different approaches of luteal phase support using low-dosage hCG or hCG-free approaches.

Luteal Phase Support in Frozen Embryo Transfer Cycles

With the improvement of the cryoconservation-techniques in the IVF-laboratory worldwide more and more frozen embryo-transfer (FET) or warmth oocyte embryo transfer-cycles are performed. This techniques could lower the treatment burden of the patient as in the event of surplus oocytes or embryos, this technique can improve the chance of a pregnancy without performing a new ovarian stimulation. Also in cases with the need of additional preimplantation genetic screening or diagnosis this technique is helpful in respect to the time needed for the genetic analysis.

In order to achieve a pregnancy, synchronization of embryo development and the endometrium is crucial. A simple way of endometrium preparation is the use of the natural cycle with endogenous production of estradiol of the growing follicle. In order to plan the correct timing for embryo thawing and transfer the LH-surge has to be detected. By the use of a natural cycle for FET, significantly higher pregnancy rates in the natural cycle are achieved as compared to modified natural cycles with application of hCG. For the natural cycle, patients have to be monitored closely by blood tests to detect ovulation and plan the thawing and transfer of the embryo(s) accordingly. To define ovulation, LH surge was deemed to have begun when the concentration rose by 180% above the latest serum value available in that patient and continued to rise thereafter. Day 1 after the LH rise, a drop of E2 and concomitant rise of $P > 1.5$ nmol/L confirmed the ovulation (Fatemi et al., 2010). Unfortunately, measurement of LH in the urine is too unreliable for accurate planning of the FET.

Contrary to a natural cycle, hCG is administered to induce ovulation and luteinization in a modified natural cycle. However, hCG-administration to end the follicular phase might have a negative effect on endometrium receptivity, as modified natural cycles result in significant lower pregnancy rates compared to natural cycles.

A frequently used approach for FET is a hormonal-replacement cycle with the administration of exogenous estradiol and progesterone. The advantages of this approach are seen in a reduced risk for cycle-variation and smoothening of the work-flow in the IVF-laboratory, as planning of the embryo-transfer is possible. Hormonal replacement cycle can be performed with or without co-treatment with GnRH agonists.

Until now, the best approach for FET is still under discussion and there is an urgent need for randomized controlled trials to compare the correctly conducted natural cycle with correct determination of LH-surge and the hormonal replacement cycle.

TECHNOLOGIES

Ultrasonography in IVF

Roger A Pierson, University of Saskatchewan, Saskatoon, SK, Canada

© 2018 Elsevier Inc. All rights reserved.

Ultrasonographic imaging is an integral part of clinical care in the assisted reproductive technologies. It is difficult to imagine how IVF was done before we had the ability to visualize the female reproductive organs easily. In the not-to-distant past, IVF was done using laparoscopic retrieval of oocytes, monitoring ovarian stimulation cycles only by hormonal assay of systemic estradiol levels, and embryos were transferred back into a uterus when we had no real idea about the physiologic status of the endometrium. Only clinical touch was used to guide the placement of the embryo transfer catheter. Ultrasonographic imaging in the hands of the individuals performing the assisted reproductive technology (ART) procedures has delivered us from those uncertainties. The quality and quantity of the information we receive from the images is an essential part of every IVF procedure. Visualization has been an intrinsic aspect of the incredible increases in ART success rates. It is important to remember that the integrated understanding of anatomy, physiology, endocrinology, and pathology we have gained with imaging in the patients undergoing IVF are as important as the incredible increase in knowledge and practice in the embryology laboratories. The confluence of, and synergy among, technologies used in ART care have greatly increased the probabilities of successful pregnancies (Pierson, 2017).

The essential uses of ultrasonography in IVF are in ovarian assessment, monitoring the course of ovarian stimulation protocols, visually-guided retrieval of oocytes, endometrial assessment, and visually-guided embryo transfer. The use of imaging in each of these areas also provides a springboard for new research areas that may be incorporated into clinical care. Awareness of new frontiers is essential to progress in ART and in understanding the changes that will surely come. We rely so heavily on imaging in general gynecology, basic infertility workups and early obstetrical care that it is a challenge to narrow the focus to IVF alone. However, ultrasonography has forever changed our understanding of female reproduction. This article is a synopsis of imaging in IVF integrated into a framework within which the highest quality of care may be provided for patients who require ART to complete their families.

Ovarian Assessment

Monitoring the Course of Ovarian Stimulation

Ovarian stimulation protocols vary tremendously and have evolved from fairly simplistic administration of exogenous hormones derived from urinary sources to sophisticated blends of GnRH analogs, recombinant FSH and LH and other compounds (Cohen, 2003). The protocols are undergoing constant refinement and are soon likely to be tailored to the physiologies of individual patients. The common denominator in all ovarian stimulation protocols is that ultrasonography is used to monitor their effects on the ovaries of each patient. High-resolution transvaginal ultrasonography allows a rapid, noninvasive and highly visual approach to following the fates of individual follicles and cohorts of follicles. When combined with our knowledge of natural ovarian physiology with concomitant assessment of circulating estradiol concentrations and oocyte development, imaging allows determination of the optimal timing for induction of the final stages of folliculogenesis and oogenesis and oocyte retrieval in each patient undergoing ovarian stimulation.

Ovarian stimulation protocols are designed to overwhelm the endogenous physiologic mechanism of selection for a single dominant follicle, obviate atresia in the cohort of other follicles recruited into the follicular wave and foster and sustain the development of many follicles to an imminently preovulatory state so that competent oocytes may be retrieved for IVF. Ultrasonography is essential in determining the numbers and fates of follicles stimulated and to tailor the ovarian response to the optimal number and quality of oocytes desired. In many cases, information such as the difference in ultrasonographically determined diameter between the largest follicle and first and other subordinate follicles may be used to assess the progress and quality of the stimulation. The follicular response of each woman, the number of oocytes desired and clinical assessment of the risk of ovarian hyperstimulation dictate modifications to the stimulation protocol. It is important to note that the expected linear relationship between circulating estradiol concentrations and follicular diameter may not exist during ovarian stimulation and that all follicles do not contribute equally to the estradiol concentrations in circulation.

Human chorionic gonadotrophin (hCG) is usually administered to trigger the final phases of follicular maturation when the largest follicle first attains a predetermined diameter (e.g., 18 mm to 20 mm). The timing of administration of hCG or recombinant LH administration is critical in initiating the final stages of oocyte maturation and establishing the time for oocyte retrieval which will yield the highest quality oocytes in the proper stage of development with the highest probability of fertilization. The relationships between follicle size and oocyte maturity remain poorly elucidated; however, oocyte competence and maturity play important roles in the ability of the resulting embryos to develop to the blastocyst stage. The timing of hCG administration varies among programs based upon individual clinician's feel for the stimulation cycle and laboratory logistics. Most commonly, 5000 IU or

10,000 IU hCG is administered, although recombinant LH also is utilized. Oocyte retrieval is then scheduled for 30–34 h thereafter. Many programs now use only ultrasonographic monitoring to determine the course of ovarian stimulation. Estradiol monitoring during the stimulation protocol seldom changes the timing of hCG administration and has not appeared to affect pregnancy rates or the risks of ovarian hyperstimulation syndrome (Lass, 2003).

The morphological characteristics, individual physiologies and most appropriate diameters of follicles that produce optimal oocytes prepared for fertilization remains the subject of intensive research. Mature oocytes yield the highest fertilization rates in standard IVF cycles; however, the wide-spread use of intracytoplasmic sperm injection (ICSI) and progress in understanding the potential of in vitro maturation and/or fertilization of immature oocytes necessitates reassessment of what constitutes an optimal oocyte. The role of ultrasonography in IVM-IVF protocols revolves around the optimal timing of oocyte retrieval for optimal fertilization and cleavage.

Ovulation in natural cycles has been reported from follicles as small as 14 mm and oocytes collected in IVF cycles from small follicles may fertilize well; oocytes have been aspirated from follicles <10 mm in diameter and matured in vitro to increase the number of transferable embryos. Through research in animal models, we know that there appears to be a correlation between computer-assisted ultrasound image attributes of follicles and the ability of the oocyte to fertilize; however, similar studies in humans have apparently not been completed. The natural synergy among these observations is the start of an emerging area of research.

Evaluation of growth rates for individual follicles may be a useful measure for prediction of the number of follicles that may develop during ovarian stimulation protocols. This information is equally important when assessing the risks of ovarian hyperstimulation. In the past, follicular growth rates during induced cycles were observed to be faster than those of natural cycles. However, a mathematical equation developed to equate follicular growth rate to follicular age was used to conclude that the growth rates of individual follicles in spontaneous cycles were similar to those recruited by exogenous gonadotropins. Reduced growth rates of follicles were observed in cycles where a pregnancy was established and it was concluded that growth rate was a more useful characteristic for prediction of ovulation than follicular diameter. Follow up work does not appear to have been done. It will be logistically challenging to combine daily detailed ultrasonographic measurements of individually mapped follicles with per follicle outcomes from the embryo laboratory and final pregnancy outcomes. New imaging based studies tracking the development trajectories of individual follicles are required.

Color flow and power flow Doppler imaging have been used to assess the state of relative maturity of dominant follicles. Intrafollicular influences on oocyte development such as the developmental competence of the oocyte, oocyte metabolism and mitochondrial function may be mediated, at least in part, by peri-follicular vascularity. It has been hypothesized that blood flow to the follicle is developmentally important for the generation of a normal follicle and oocyte (Borini et al., 2001). Preliminary studies using various indices of follicle vascularity support the notion that women who received embryos originating from oocytes nurtured in well-vascularized follicles had a higher pregnancy rate than women who received embryos derived from oocytes from more poorly vascularized follicles.

Assessment of Ovarian Follicular Reserve

Changes in demographic trends in the age at first pregnancy in our society have continued to yield more and more women seeking pregnancy when they are older and consequently less fertile. It is well documented that fertility declines progressively as age advances (The American College of Obstetricians and Gynecologists Committee on Gynecologic Practice and The Practice Committee of the American Society for Reproductive Medicine, 2014). In IVF, much attention is on assessment of the ovarian reserve. Ultrasonography is a significant part of the tests now being used to investigate follicular dynamics in aging women as are detailed endocrine based tests (Practice Committee of the American Society for Reproductive Medicine, 2015). A decrease in the ovarian reserve, or number of follicles capable of being stimulated, is a primary reason for declining fertility. Similarly, the ovarian response to exogenous gonadotrophin stimulation also decreases, but the range of individual variation is extremely wide and it is well known that age is only a rough guesstimate of the ovarian reserve and hence the ovarian stimulation response.

There are several tests of “ovarian reserve” (Practice Committee of the American Society for Reproductive Medicine, 2015). Ultrasonography may be used to estimate the number of antral follicles at specific times of the menstrual cycle and provides useful information. Ultrasound assessments take place using antral follicle counts or measurement of ovarian volume. Early follicular phase antral follicle counts, typically done on day 3–day 7 postmenstruation, may be used to predict the number of follicles likely to develop during ovarian stimulation. Women having fewer than 5 follicles under 10 mm in diameter before ovarian stimulation begins have a relatively poor prognosis for success. Studies to determine the extent to which antral follicle counts correlate with endocrinologic measures of ovarian reserve (e.g., cycle day 3 follicle-stimulating hormone (FSH) and estradiol concentrations) remain to be widely confirmed. Ovarian volume assessments are based on the presumption that there is a significant correlation between the population of primordial follicles remaining in the ovary and the volume of the ovary, measured using either 2- or 3-dimensional ultrasonography. A clear relationship has been demonstrated between decreased ovarian volume and antral follicle counts and advancing age combined with increased FSH. There remains a good deal of work yet to do in order to standardize the imaging based assessments; however, ultrasonography remains an important aspect of ovarian reserve estimation and relating this knowledge to successful ovarian stimulation cycles.

Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome (OHSS) is an exaggerated ovarian response to ovarian stimulation that can develop into a life-threatening complication. In women with the disorder, ultrasonography demonstrates grossly enlarged ovaries containing

numerous large follicular cysts with thin, highly hyperechoic borders, and dramatically increased local blood flow (Battaglia et al., 2004). The ovaries may enlarge to diameters in excess of 10 cm and echotexture interpreted as intrafollicular hemorrhage in some of the large cysts frequently may be observed. In severe cases, the ovaries may become too large to visualize in their entirety with transvaginal ultrasonography and transabdominal imaging must be used. Serial TVUS during ovarian stimulation cycles and careful tailoring of the dose of exogenous gonadotrophins has helped to limit the risk of OHSS; however, prevention of OHSS is multifactorial and requires ovarian stimulation protocols tailored to patient specifics and close monitoring of the ovarian response. Clinicians take an active role in the prevention of OHSS by abandoning the treatment cycle, coasting strategies during stimulation, the use of low doses of ovulation triggering agents and/or cryopreserving all embryos and single embryo replacement in subsequent cycles. When OHSS does occur, torsion of an enlarged ovary is a complication that must be kept in mind. When torsion is suspected, color flow Doppler imaging can help to establish an early and accurate diagnosis.

Computer Assisted Ultrasonographic Imaging of Follicular Development

Computer-assisted image analysis is expected to have the potential to aid in the identification of healthy versus atretic follicles in natural and ovarian stimulation cycles. Physiologically dominant ovarian follicles are identifiable by ultrasonography at approximately day 7 post menstruation in unstimulated cycles and ovulatory and nonovulatory follicles were identifiable in ovulation induction cycles (Baerwald et al., 2012). The image attributes of ultrasonographic images of normal preovulatory follicles include thick, low-amplitude walls and a gradual transformation zone at the fluid-follicle interface. The walls of preovulatory follicles are characterized by increased heterogeneity, increased wall breadth and a more gradual transformation at the fluid-follicle wall interface. Atresia is characterized by thin walls, high numerical pixel value (bright) signals and highly variable signals from the follicular fluid. Evaluation of the acoustic characteristics indicative of viability and atresia combined with the elucidation of the stage of oocyte development for optimal fertilization is an active area of research that has significant implications for development of safer and more effective ovarian stimulation protocols.

Ultrasound-Guided Oocyte Retrieval

The most compelling use of imaging in IVF has been the tremendous advances facilitated by transvaginal retrieval of oocytes. Oocyte retrieval was a technology limiting step in the early days of IVF. Retrievals were done laparoscopically or using ultrasound guidance from transurethral, transvesicular or transabdominal imaging. Transvaginal imaging and concerted efforts to develop effective, accurate tracking of the needles used for follicle aspiration was probably the single most important step in making IVF as safe and effective as it is. Clinical complications appear to be rare.

Retrieval of oocytes in IVF cycles is now routinely performed under TVUS guidance. An aspiration needle is introduced through a guide attached to a transvaginal probe and is inserted into first one ovary, then the other, via the vaginal fornices. Almost all aspiration needles now in use have a small band of highly reflective surface near the tip of the needle to facilitate visualization as the needle enters the ovary and once it is in the follicles (Fig. 1A). The highly reflective echoic tip of the needles makes identifying their path quite easy and the path of the needle may be accurately visualized within biopsy guidelines imposed on the ultrasound screen as it is guided into each ovarian follicle. The needle tip can be observed directly as it is maneuvered within the ovaries and into each follicle (Fig. 1B). The follicular fluid containing the oocyte/cumulus complex is then aspirated by application of gentle suction. The walls of the follicle collapse as the fluid is aspirated and the needle moved within the follicle to ensure that all of the follicular fluid is withdrawn (Fig. 1C).

There are two main types of aspiration needles used for oocyte retrieval, single and double lumen needles. Single lumen needles typically have a smaller diameter and tend to cause less discomfort. In many, if not most, IVF centers follicle aspirations are done using single lumen needles and no follicle flushing. The double lumen needles were developed for a technique involving constant infusion of oocyte collection media into the follicle at the same time as the follicular fluid was being removed. The double lumen flushing technique was thought to increase the turbulence within the follicle, assist in dislodging the oocyte-cumulus complex from the follicle wall and increase the chances of oocyte collection. Single lumen needle flushing techniques may also be used. In this technique, all of the follicular fluid is first aspirated from the follicle and the follicle is then refilled with collection medium and re-aspirated. A back and forth motion on the plunger of the infusion syringe may be used to increase the turbulence of flow. Follicular flushing increases the procedural time required and no significant differences have been observed in live birth rate, clinical pregnancy rates, and the number of oocytes retrieved between flushing and nonflushing techniques for oocyte retrieval.

New types of follicle aspiration needle sets are under development and smaller diameter needles are under evaluation. Needle diameter does not affect oocyte yield, however, the time required for oocyte retrieval procedures was prolonged when smaller diameter needles were used. Similarly, equivalent oocyte retrieval numbers have been obtained using needles designed for aspiration of small follicles in an in vitro maturation (IVM) program.

Unsuccessful oocyte retrieval following apparently normal ovarian stimulation reportedly occurs in 1%–7% of cycles—the so-called “empty follicle syndrome.” The etiology appears to be multifactorial and may involve both technical and biological mechanisms. However, there is significant controversy over whether or not the syndrome actually exists and the nature of its prevalence and putative causative factors.

The complication rates of transvaginal ultrasound-guided oocyte retrieval are reportedly extremely low and almost all procedures are performed under conscious sedation on an outpatient basis.

Fig. 1 Ultrasound images taken during oocyte retrieval (A,B,C). (A) The highly echogenic band around the distal end of the needle and the tip of the follicle aspiration needle are clearly visualized in the superior most follicle. The needle is maneuvered within the ovary to aspirate all follicles. (B) Following complete evacuation of the follicular fluid, the echoic tip of the needle is visualized within the apposed walls of the collapsed follicle. (C) The hyperechoic area of the former follicle is visualized following follicle aspiration and removal of needle. Images courtesy of Alex Hartman. Reprinted with permission from Pierson, R. A. (2017). *Ultrasonography in IVF*. In: Gardner, D., Simón, C. (eds.) *Handbook of in vitro fertilization* (4th edn.), pp. 81–103. London, UK: CRC Press. ISBN 9781498729390.

Assessment of the Endometrium at Embryo Transfer

Endometrial Thickness and Pattern for Assessing Endometrial Receptivity

Ultrasonography has been used, with varying degrees of success, to correlate the probability of pregnancy in ovarian stimulation–ovulation induction cycles and IVF cycles (Bonilla-Musoles et al., 2013). Most imaging studies attempt to predict the probability of implantation based on simple biophysical measurements of the endometrium. A thicker endometrium was observed on the day of oocyte retrieval in women who conceived during that cycle. In other studies, no correlation was observed among endometrial pattern, thickness, estradiol levels, number of oocytes retrieved, or progesterone level on the day of embryo transfer. Contradictory reports, and a lack of correlation between ultrasonographic endpoints and histologic staging of the endometrium in women undergoing IVF can be interpreted to mean that ultrasonography using simple biophysical measures is not sensitive enough to be useful in predicting endometrial receptivity and the probability of implantation with the exception of a strong negative correlation when the endometrium is thin. It is also possible that inconsistencies in the day on which measurements were done among the many studies, differences in measurement techniques and the use of a wide variety of ovarian stimulation protocols which affect endometrial development differently have played a role in our seeming inability to interpret the data. Consensus is that implantation is more likely to occur as long as the endometrial thickness is >6 mm.

Collections of fluid are sometimes found within the uterine lumen on the day of embryo transfer. Approximately 5% of cycles may be compromised by the presence of lumen fluid accumulation at some time during the IVF cycle procedures and in 2% of the cases the fluid accumulations persist until the day of embryo transfer. The pregnancy rate among women with fluid accumulations is markedly lower than for those who did not exhibit intraluminal fluid. Fluid accumulations have been found in almost three times

as many women with tubal factor infertility compared with other causes. Although luminal fluid collection does not appear to be a common problem in IVF cycles, it does appear to have a negative impact on implantation and pregnancy rates.

Spectral Doppler and Color Flow Doppler Ultrasonography

The history of Doppler ultrasonography of the uterine arteries in the literature is confusing because of many reports failed to differentiate between spectral Doppler and color flow Doppler imaging. Early studies tend to be based upon spectral Doppler examinations, which are a means of evaluating the resistance to blood flow using calculations of the pulsatility index (PI), resistance index (RI), $V_{\max}$ or the systolic to diastolic ratio (S/D ratio). Color flow Doppler and power flow Doppler imaging are means of turning motion, either toward or away from the transducer in the case of color flow Doppler, or motion in any direction in the case of power flow Doppler, into a visually detectable color overlay on the two-dimensional ultrasound image.

Initially, attempts to determine if evaluation of blood flow in the uterine arteries could be useful were based on RI to look for differences in uterine receptivity. No differences were found among women who conceived and those who did not. However, elevated PI in the uterine artery has been associated with lower pregnancy rates. Assessments of uterine artery RI have remained inconclusive, except that absent or low diastolic flow was associated with failure to conceive. Uterine artery vascular impedance measured by RI has not been found to be useful for predicting the probability of pregnancy. Some ultrasonographically detectable criteria were observed to be associated with negative pregnancy outcomes; however, no prognostic value has been observed in any measurement of vascular perfusion.

Power flow Doppler ultrasonography has been used to investigate endometrial receptivity and flow calculations showed that evidence of motion indicative of vascular flow of $<5 \text{ mm}^2$ were associated with lower pregnancy rates. Endometrial and subendometrial perfusion are reportedly impaired in women with unexplained infertility. In one report, spiral arterial flow and uterine artery flows were not different between pregnant and nonpregnant women; however, if spiral arterial flow could not be detected, no conceptions were observed.

Imaging-Based Uterine Scoring System

Imaging-based scoring systems to predict uterine sensitivity based on uterine biophysical profile system have been proposed. The scoring systems were designed by assigning “points” for various criteria and then adding the cumulative columns to compute a score. Comparisons of uterine scores in conception with nonconception cycles demonstrated no differences in any criteria measured, including endometrial thickness, endometrial pattern, PI, RI, color Doppler, and other vascular indices. However, in more recent work, a new endometrial scoring system based up two-dimensional imaging parameters and creation of a 3-dimensional mathematical surface for visual analysis has shown promising results in the ability to predict the probability of implantation from images taken on the day of oocyte retrieval.

Three-Dimensional Imaging of the Endometrium

Three-dimensional (3D) ultrasonography first became available in the late 1990s and 3D is now a part of almost all high-end imaging systems. There are several methods used to provide 3D information and there are no studies comparing the same endpoints with different imaging systems (Pierson, 1999). Descriptive studies of endometrial development during the menstrual cycle have been done and provide an excellent reference for the normal changes in 3D volumes. The prospects for predicting the probability of implantation in IVF programs have now extended into 3D exploration of endometrial receptivity and optimal embryo replacement location.

The role of three-dimensional volumes as predictors of endometrial receptivity and implantation is contradictory (Alcazar, 2006). Endometrial volumes compared among women who conceived and those who did not showed that pregnancy and implantation rates were lower in women with volumes of $<2 \text{ mL}$. No pregnancies were established when endometrial volumes were $<1 \text{ mL}$. However, a contemporary study found no relationship between 3D volume of the endometrium and conception. Nor was a correlation found among estradiol levels, endometrial thickness, or endometrial volume leading to the conclusion that there was no predictive value for conception in assessing endometrial volume. Endometrial thickness and endometrial volumes were not correlated with probability of pregnancy; however, 3D power flow Doppler indices used to measure endometrial perfusion may have some predictive value although definitive studies do not appear to have been completed. Spiral artery blood flow measurements in 3D had positive predictive value when performed on the first day of ovarian stimulation, while women who became pregnant had lower RI and a higher 3D flow index than those that did not. Taken together, these observations provide rationale for further investigation of 3-dimensional ultrasonography in all of its iterations, however, it is clear a predictive index is beyond the limits of our current technology.

Motion Analysis

Motion analysis, or direct measurement of subendometrial contractions, is a method of evaluating the endometrium based on the observation that the uterus and endometrium are in constant motion (van Gestel et al., 2003). Objective assessment of these contractions has now been applied to assisted reproduction cycles. Endometrial contractions may have a predictive effect on the

probability of pregnancy in IVF cycles. Women with a higher frequency of uterine contractions were found to have lower pregnancy rates. However, contradictory evidence also has been reported. Exogenous progesterone has demonstrably reduced uterine contractility on the day of embryo transfer and it has been hypothesized that progesterone supplementation before embryo transfer may improve endometrial receptivity by lowering the possibility that embryos might be expelled from the uterus by contractions. Uterine contractility at the time of blastocyst transfer was lower and reached a nadir 7 days after hCG administration in IVF cycles. Lower amplitude and frequency of contractions is hypothesized to facilitate blastocyst implantation. The effects of progesterone on uterine contractions have been demonstrated by the observation that higher progesterone concentrations correlated with lower amplitude and frequency uterine contractions. It was suggested that progesterone could be administered to reduce endometrial contractions and have a positive impact on pregnancy rates although this hypothesis does not appear to have been critically tested. The results of pharmaceutical intervention remain under investigation at this time.

Ultrasound-Guided Embryo Transfer

Ultrasonographic imaging is frequently used to guide the placement of the embryo transfer catheter in an effort to facilitate optimal embryo placement and enhance the probability of a successful pregnancy (Mansour and Aboulghar, 2002). Transabdominal ultrasound guidance is a more common means of directing the embryo transfer catheter, however, transvaginal scanning may also be used. It is also important to note that ultrasound guidance of embryo replacement does not prevent the establishment of an ectopic gestation. The recent advent of easy to use and relatively inexpensive three-dimensional ultrasonography has facilitated a new wave of inquiry into the utility of 3D imaging to guide the embryo transfer catheter (Gergely et al., 2005). Early impressions are that 3D imaging may be beneficial in identifying the site of optimal embryo placement with respect to anatomic variations in individual women.

Clinical and laboratory preparations for embryo transfer are the same, regardless of whether the transfer is to be ultrasound guided or not. Patients are placed in the lithotomy position and the cervix exposed using a bivalve speculum. Mucus and secretions are removed using culture media and the tip of the transfer catheter is introduced into the os cervix. The addition of transabdominal ultrasound imaging simply involves placement of the transducer, typically using a 3–4 MHz large aperture probe, on the lower abdomen and pelvis in the sagittal plane and imaging the full sagittal plane of the uterus and cervix through a full bladder window (Rijnders et al., 2000; Tang et al., 2001; Matarras et al., 2002) (Fig. 2). Most standard embryo transfer catheters are easily visualized as a pair of highly echogenic lines within the cervix; however, transfer catheter systems are undergoing constant refinement and new systems have been developed to increase the ease of imaging.

Once the catheter has been identified, the tip may be carefully guided through the uterine lumen using real-time imaging. Once the clinician attains the optimal place with the uterus, the embryos are gently expelled into the lumen. Opinion on exactly what optimal placement means is varied. The fluid droplet containing the embryos is visualized as a very small hypoechoic blip deposited at the tip of the transfer catheter. Specular reflection artifacts may sometimes be helpful in its identification (Fig. 2B).

Fig. 2 Mid-sagittal view of the uterus imaged with transabdominal ultrasonography during embryo transfer (A,B). (A) The bladder is fluid-filled, hypoechoic and fills the upper aspect of the image. The uterus is seen in mid-sagittal plane and the transfer catheter is visualized as the highly echogenic line in the middle of the uterus. (B) Enlargement showing the microdroplet of media containing the embryo visualized approximately 6 mm from the endometrial/myometrial interface at the fundal aspect of the uterus (hyperechoic focal point). Specular echoes enhance the ability to visualize the microdroplet. The tip of the embryo transfer catheter is visualized to the right of the microdroplet as it is slowly removed from the lumen. The images document optimal replacement of the embryos. Image courtesy of Dr. Alex Hartman. Reprinted with permission from Pierson, R. A. (2017). Ultrasonography in IVF. In: Gardner, D., Simón, C. (eds.) *Handbook of in vitro fertilization* (4th edn.), pp. 81–103. London, UK: CRC Press. ISBN 9781498729390.

Transvaginal ultrasound guidance is done in a similar fashion, except that a probe designed for intracavitary use is introduced through the speculum and placed into contact with the anterior vaginal fornix. The transfer catheter is visualized and the tip guided to the optimal uterine location for embryo deposition. No differences in pregnancy rates were observed when transabdominal versus transvaginal ET catheter guidance was evaluated. The choice of imaging approach is left to individual clinicians assessment of uterine position, parity and their own level of comfort with the procedure.

There is a measure of controversy regarding the usefulness of ultrasonographic guidance during embryo transfer versus nonvisually guided clinical touch. Some clinicians prefer to rely on ultrasound guidance for mock transfers in cycles before IVF and embryo transfer and clinical touch in the actual procedure using physical measurements taken during the mock cycle. Others prefer to use ultrasound guidance for all procedures, and still others make a decision regarding its use based on whether or not the transfer is likely to be classified as easy or difficult. Three- and four-dimensional ultrasonography have been posited as an optimal means of identifying a “maximal implantation point (MIP)” (Gergely et al., 2005). It was reported that identification of the MIP was easily and reliably done using ultrasonographically identifiable anatomic markers that could be individualized for each patient and the ET catheter guided to it.

Concluding Remarks

Ultrasonography has provided us with direct visual access to all of the events involved in natural human reproduction and has allowed us to elucidate our natural reproductive processes. When we contemplate the incredible progress made in our ability to understand assisted reproduction, it seems strange to envision ART care without ultrasound imaging. We take for granted the ability to see the effects of ovarian stimulation and optimize the protocol for individual patients, easy accessibility of the ovaries for oocyte retrieval, direct visualization of the endometrium at the time of embryo transfer and embryo replacement under direct visual guidance.

One of the most joyous occasions we have in our work is when we are able to confirm pregnancy in our patients. There is little that approaches the drama in the imaging suite when we can point out an embryo to our patients and listen to the heartbeat of their new life. The combined contributions to ART made by the dramatic advances made in the embryo laboratory, enhanced clinical knowledge, and advanced imaging techniques enrich the not only our discipline and scientific knowledge, but also the lives of many couples who have struggled with infertility.

Egg and Embryo Donation

Irene Woo and Richard J Paulson, Keck School of Medicine of the University of Southern California, Los Angeles, CA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Egg and embryo donation are now standard components of care offered by infertility specialists. Initially intended as therapy for women with premature ovarian failure, or those with heritable genetic defects, the use of egg donation has been extended to women with a variety of defects in egg production or function. The number of donor egg cycles has significantly increased in the past decade; the North American Society for Assisted Reproductive Technology (SART, 2015) registry reported 20,435 cycles in 2015. Currently, women with age-related decline in fertility represent the largest group of women undergoing treatment with egg donation. Embryo donation is also a practical option for couples with female and male factor infertility who may need both egg and sperm donation. Frequently with in vitro fertilization (IVF) practices, more embryos are created than can be used. Couples who have completed their reproductive attempts may desire to donate the cryopreserved embryos to other individuals attempting to build a family (ASRM, 2013c). In 2015, SART reported 1428 cycles using donated embryos.

History

The first reports of human egg donation appeared in 1983. Trownson et al. (1983) reported a pregnancy after the donation of an oocyte by an infertile woman undergoing IVF. The donor had undergone controlled ovarian stimulation (COS) and the recipient had ovulated at the same time as the donor underwent egg retrieval. One of the recovered oocytes was donated to the recipient, and was inseminated with the recipient's husband's sperm. The resulting embryo was then transferred to the recipient, who became pregnant, but then miscarried. In a subsequent attempt, a single oocyte was again donated by an IVF patient, this time to a woman with premature ovarian failure (Lutjen et al., 1984), whose uterus was prepared with a combination of oral estradiol and vaginal progesterone. The recipient became pregnant and carried the pregnancy to term, thus becoming the first successful instance of egg donation.

During the same time period, a group working at Harbor-UCLA in the United States developed a technique called "ovum transfer." In this process, the egg donor was inseminated with the recipient partner's sperm at the time of the luteinizing hormone (LH) peak. Donors and recipients were matched on the basis of synchronous ovulation. Five days later, the donor's uterine cavity was lavaged in an effort to recover the fertilized blastocyst, which was then transferred to the uterus of the infertile patient. The technique resulted in a pregnancy and subsequent delivery of a child genetically similar to the donor (Bustillo et al., 1984). Unfortunately, this technique was inefficient and efforts to increase the embryo yield by administering COS to the donors led to retained pregnancies in the donors (Sauer et al., 1989a).

Egg donation quickly became the obvious treatment of choice for women with premature ovarian failure. The landmark event of pregnancy in a woman without ovarian function substantiated the hypothesis that exogenous estrogen and progesterone could reliably produce a receptive endometrium (Devroey et al., 1989a,b). In women with residual ovarian function, donor and recipient cycles could thus be synchronized with gonadotropin-releasing hormone (GnRH) agonists and the recipient endometrium stimulated with exogenous steroids (Sauer et al., 1989b, 1991). These essential principles have remained the key components of the current practice of egg donation.

The first published study on embryo donation was a report of an embryo created with donated sperm and donated eggs made specifically for the recipient (Van Steirteghem et al., 1987). When the first true embryo donation occurred is not known, however in the mid-1980s, it was in common usage (Devroey et al., 1989a,b). During this time, the term "embryo adoption" was also coined. While some may use the term embryo adoption and embryo donation synonymously, the transfer of an embryo is legally considered a property transfer and not an adoption (Wurmbbrand, 1986). The American Society for Reproductive Medicine (ASRM) ethics committee discourages the use of the term "adoption" as inaccurate (ASRM, 2016). Nevertheless, there are several "embryo adoption agencies" in the USA, which serve to match prospective donors and recipients and allow for the transfer of embryos which would otherwise be discarded. The medical and technical aspects of embryo donation and similar to those of oocyte donation, and may be simpler without the need for cycle coordination if one is using cryopreserved embryos.

Indications

Women whose eggs are not capable of producing a pregnancy may use egg donation as a means to become pregnant. In addition to premature ovarian failure, indications for egg donation include cases of poor egg quality presumed from multiple failed cycles of conventional IVF, women of advanced reproductive age with associated diminished ovarian reserve, and cancer survivors with premature ovarian failure secondary to chemotherapy. Patients with gonadal dysgenesis are appropriate candidates for egg donation. Those with Turner's Syndrome may conceive, but are at higher risk of obstetrical complications (Hagman et al., 2013). Other patients may choose egg donation to avoid passing heritable genetic diseases to their children, although

preimplantation genetic diagnosis (PGD) is increasingly being applied in these situations. In certain social situations such as same-sex male couples, use of donor oocytes and gestational surrogates is also indicated. For couples with both female and male factor infertility that would require both an oocyte and sperm donor, embryo donation is a practical option. Embryo adoption is also more cost effective than coordinating a fresh oocyte donor with in vitro fertilization (Finger et al., 2010).

Prognostic Indicators

Donor Age

The chronological age of the egg donor is one of the principal factors in the overall success and live birth outcome of oocyte recipient cycles (Sauer et al., 1990; Navot et al., 1991). The mean donor age in the United States is approximately 26–28 years (Kawwass et al., 2013). In a large population study, the highest live birth rate in recipients was achieved in cycles with donors ≤ 34 years of age, while recipients with donors aged 35–39 were significantly less likely to achieve a live birth (Wang et al., 2012). Egg donors are usually healthy and without a history of fertility treatment themselves. Whereas prior fertility in a donor is not necessary, previous successful cycles may improve the prognosis in subsequent ones (Harris et al., 2002). Similarly, for embryo donation, the age of the female at the time of the original oocyte retrieval is one of the main influence on success.

Recipient Age

Recipient age does not appear to decrease the probability of pregnancy success with egg donation or embryo (Paulson, 2014). Physiological observations have shown that uterine blood flow and the endometrial response to exogenous steroids do not appear to diminish with age (Sauer et al., 1993a). In a large clinical study, similar rates of pregnancy and live birth rates were achieved among fresh oocyte recipients aged <35 , 35–39, 40–44, and ≥ 45 years (Wang et al., 2012). An analysis of the national registry data suggested a modest decline in live birth rates after 45 with still poorer outcomes after age 50 (Toner et al., 2002; Yeh et al., 2014). However other studies have shown similar pregnancy success with oocyte donation after the age of 50 (Sauer et al., 1993b; Paulson et al., 1997).

Recipient Factors

Egg donation is successful irrespective of most causes of infertility in the recipient (Garcia-Velasco et al., 2003; Paulson et al., 1997; Harris et al., 2002). The main exceptions are associated with uterine pathology. For instance, Asherman's Syndrome or previous radiation therapy may negatively impact uterine receptivity (Teh et al., 2014). Analogously, uterine fibroids, specifically submucosal fibroids or fibroids that distort the cavity, have been shown to decrease embryo implantation rates and therefore should be resected (Shokeir et al., 2010). Hydrosalpinges should be also be removed as these have been shown to decrease implantation rates and increase the risk of infection as well as ectopic pregnancy in recipients of egg donation (Cohen et al., 1999). Neither endometriosis nor adenomyosis in recipients appear to negatively impact embryo implantation (Pellicer et al., 2001; Martinez-Conejero et al., 2011). Obesity has been associated with decreased odds of pregnancy in women undergoing IVF with autologous oocytes, however its effect on oocyte donation models have been variable (Soares et al., 2008). A recent systematic review noted no negative impact of recipient BMI on embryo implantation, miscarriage, or live births (Jungheim et al., 2013). Heavy tobacco smoking has been shown to reduce uterine receptivity with a significantly lower pregnancy rates in oocyte donation models and therefore patients should be advised to quit smoking (Soares et al., 2007).

Repetitive Cycles

Among recipients with a normal uterine cavity, one failed cycle does not necessarily negatively impact the outcome in subsequent cycles—pregnancy rates are comparable on a per cycle basis (Paulson et al., 1997). Cycle fecundability also appears to be unaltered by the number of cycles that the donor has undergone. The donor response to gonadotropin therapy, the number of oocytes produced, and pregnancy rates have been reported to be unimpaired after successive stimulation cycles (Jain et al., 2005).

Oocyte Donor Screening

Guidelines for donor screening are periodically updated and published by the American Society for Reproductive Medicine (ASRM, 2013c). The guideline attempts to incorporate information from the US Center for Disease Control and Prevention (CDC), the US Food and Drug Administration (FDA), and the American Association of Tissue Banks (AATB). However individual state practice requirements may differ and these must be followed. Oocyte donor screening generally includes a personal and sexual history and physical examination, with the intent of excluding those women at high risk for HIV, other sexually transmitted disease, transmissible spongiform encephalopathy, or recent confirmed or suspected West Nile Virus infection (ASRM, 2005, 2013c). For a complete list of screening questions and exclusions, see "Uniform Donor Application" at www.sart.org. The FDA also requires the following laboratory tests be performed within 30 days of oocyte collection: serum screening for syphilis, hepatitis B and C,

HIV-1 and HIV-2. *Neisseria Gonorrhoeae*, Chlamydia, and blood type and Rh factor are also recommended. Psychological screening should include a family, sexual, substance use, and psychiatric history along with assessment of stability, motivation to donate, life stressors and coping skills, and interpersonal relationships. The counselor should confirm that the donor has been informed of the medical treatment, discuss the psychological risks of egg donation, and evaluate for signs of coercion.

Genetic screening should elicit any personal or family history of any Mendelian disorders, major malformations due to multifactorial causes, or known karyotypic abnormalities. A screening test for cystic fibrosis is recommended in all donors, and heterozygotes may be included as a donor if the recipient is aware and the recipient's partner tests negative (Zenke and Chetkowski, 2002). Specific ethnic groups known to be at high risk for carrying certain recessive genes should undergo additional screening tests. It is not appropriate to screen donors for adult onset conditions (such as cancer predisposition, Huntington disease, etc.) without full consent of donor including formal genetic counseling (ASRM, 2013c).

Recipient Screening

As with donors, the ASRM periodically updates its guidelines for the screening of recipients (ASRM, 2013c). Routine screening includes a medical and reproductive history, physical exam, and standard preconception testing and counseling. Blood type and Rh factor, rubella and varicella titers (with vaccination if not immune) along with infectious disease screening is often obtained in addition to standard preconception laboratory evaluation. Recipients should undergo counseling regarding the potential psychological implications of becoming parents as a result of egg donation (ASRM, 2004).

Prior to embryo transfer the uterine cavity should be carefully evaluated and any pathology corrected. Evaluation of the endometrial cavity can be achieved by saline-injection sonography (Lindheim and Sauer, 1998), hysteroscopy, or hysterosalpingography (HSG). The advantage of HSG lies in its ability to visualize the fallopian tubes and thus detect the presence of hydrosalpinges. Furthermore, potential recipients over the age of 45 should undergo thorough medical evaluation (including cardiovascular testing) and a high-risk obstetric consultation due to concerns for obstetrical complications in the very advanced maternal age women. Turner's syndrome patients should undergo echocardiography or thoracic MRI because the risk of death from aortic rupture or dissection during pregnancy may be 2%. Any significant cardiac abnormality in these patients is an absolute contraindication for attempting pregnancy (ASRM, 2012).

Embryo Donor Screening

Eligibility of the donated embryo is based on the eligibility of the gamete donors. Anonymous donors must meet all the FDA screening and testing requirement for the respective sperm donor and oocyte donor. However, often the embryos donated are created for sexually intimate partners desiring to become pregnant and only at the conclusion of their reproductive attempts are the additional embryos donated. In these situations, donors may be rescreened and tested as per FDA recommendation-but recipients must be informed that the testing was performed after the embryos were created and cryopreserved. Besides signing an informed consent relinquishing all rights of the embryo, donors should not receive compensation for the donated embryos (ASRM, 2013c).

Stimulation

Oocyte donors undergo controlled ovarian stimulation in a similar manner to that of conventional IVF. As with conventional IVF, the use of antagonists in donor cycles reduces the amount of gonadotropins required and duration of treatment (Sauer et al., 1997). Studies comparing agonists and antagonists in oocyte donation cycles have shown comparable pregnancy and live birth rates achieved with either protocol (Bodri et al., 2006). In oocyte donation cycles, an antagonist protocol also has the advantage of the option to use GnRH agonist as an alternative to an HCG trigger for oocyte maturation in patients with a high risk of OHSS (Erb et al., 2010).

In our clinic, donors are often prescribed oral contraceptives prior to stimulation in order to coordinate with the recipient cycle. Oral contraceptives are begun on day 3 of menses, and donors are evaluated on the fourth pill free day to confirm down-regulation by ultrasound evaluation of the ovaries and endometrium. Stimulation is achieved using human menopausal gonadotropins alone or in conjunction with recombinant FSH. Patients return on the fifth day of stimulation for an ultrasound and measurement of serum estradiol. Depending on provider preference, the GnRH antagonist may be given either as a fixed protocol (starting on the sixth day of stimulation) or as a flexible protocol (starting when the leading follicle reaches approximately 14 mm in size). Once two follicles achieve 18 mm in size, ovulation is triggered with a GnRH agonist and oocyte retrieval is performed approximately 34–35 h later.

Donor cycles require vigilance on the part of the nursing staff to ensure adherence to the protocol. Donors should also be encouraged to abstain from unprotected intercourse from the onset of stimulation until the following menses, and prescribed some form of contraceptives to initiate with menses to prevent undesired pregnancy.

Donor Safety

It is rare for oocyte donors to have any serious complications with the stimulation or retrieval. < 1% of donors experience events requiring hospitalization or emergent intervention during or following aspiration as a result of any cause, including severe ovarian hyperstimulation syndrome (OHSS), reactions to anesthesia, pelvic infection, and intraperitoneal hemorrhage (ASRM, 2014). The use of GnRH agonist triggers with an antagonist protocol as previously described has virtually eliminated the development of OHSS. Furthermore, since donors do not conceive during the cycle, they have the advantage of avoiding pregnancy-related exacerbations of OHSS (Morris and Paulson, 1994). Patients that are at high risk for OHSS may be treated prophylactically with cabergoline (Tang et al., 2016). In our practice, donors at risk for OHSS are also evaluated in our office 2 days after follicle aspiration. If necessary, additional intravenous fluids (1000–2000 mL of normal saline) may be administered. Rarely, paracentesis may be required in cases of severe OHSS (Aboulghar et al., 1990).

Little is known about the effect of egg donation on future health and fertility.

Large studies have shown no increase in ovarian cancer risk between subfertile women who received treatment for infertility and subfertile women who were not treated (Venn et al., 1999) or when compared to women in the general population (Siristatidis et al., 2013). Data on breast cancer risk following fertility treatment has been more controversial with some studies showing a minimal increased risk (Reigstad et al., 2015) while others showing no increased risk when compared to other subfertile women (Lerner-Geva et al., 2012). However, no studies have evaluated these risks in oocyte donors, who in general are healthy and do not suffer from subfertility. Given the absence of clear evidence, ASRM recommends limiting donors to six cycles (ASRM, 2014).

Recipient Cycle

The objective of the recipient cycle is to prepare the endometrium for implantation and to synchronize endometrial progress with embryo development. Studies to date have repeatedly shown that estradiol (E2) and progesterone (P) are the only hormones needed to generate a receptive endometrial environment (Navot et al., 1986; Paulson, 2011). Our practice utilizes the regimen depicted in Table 1. If there are concerns regarding the endometrium's ability to produce an adequate response to the exogenous steroids, a practice cycle may be performed. In a practice cycle, the preparation of the recipient endometrium with E2 and P is identical to the actual recipient cycle except on the 7th day of progesterone administration, an endometrial biopsy is performed. The biopsy may document a lack of adequate E2 priming or out-of-phase endometrium. When practice cycles provide information on adjusting timing of embryo transfer, improved pregnancy rates have been noted (Potter et al., 1998).

Recipients with ovarian function should undergo pituitary down-regulation with a GnRH agonist to avoid untimely uterine bleeding associated with fluctuating steroid levels, whereas those with ovarian failure can initiate a cycle at any time.

There are a variety of estradiol regimens, using different routes of administration as well as duration of administration. Despite the extensive hepatic first-pass effect, oral E2 is the most commonly utilized preparation. Oral E2 is converted to estrone (E1) and estrone sulfate (E1S), both weak estrogens with lower binding affinity for the estrogen receptors when compared to E2. Parenteral routes: transdermal, IM, or vaginal can bypass this hepatic first-pass effect. Although transdermal absorption of E2 may be highly variable, it produces a stable steady-state level of serum E2 (Paulson, 2011). Vaginal E2 administration results in high endometrial tissue levels due to local uptake but the serum levels are also very high (Tourgeman et al., 1999; Tourgeman et al., 2001) and it is therefore usually reserved for patients when the other routes are not effective.

Estrogen for endometrial priming can also be provided in a variable or fixed regimen with comparable efficacy. In our clinic, we increase the E2 to mimic the natural pattern of E2 levels in the circulation (see Table 1). Fixed regimens using 4 or 8 mg oral E2 per day without GnRH agonist downregulation have been used to successfully achieve an endometrial thickness > 6 mm within 5–7 days and with good pregnancy rates (Shapiro et al., 1993). Prolonged duration of E2 therapy does not appear to have a negative impact as E2 administration of 4–5 weeks have resulted in pregnancies (Tourgeman et al., 2001). A Cochrane review and a 2013 systematic review reported there was insufficient data to support one particular protocol for endometrial preparation over another (Glujovsky et al., 2010; Groenewoud et al., 2013).

Following estrogen priming, progesterone prepares the endometrium for implantation. E2 stimulates both endometrial proliferation and the induction of progesterone receptors. Therefore, an endometrial biopsy taken during a practice cycle that shows little or no progestational effect has, in our experience, been primarily reflective of inadequate estrogen priming rather than

Table 1 Standard estrogen and progesterone replacement regimen (Authors' institution)

	<i>Micronized estradiol (oral administration)</i>	<i>Micronized progesterone (vaginal administration)</i>
Days 1–7	2 mg BID	
Days 8–14	2 mg TID	
Days 15–28 (through 13th week of gestation)	2 mg BID	200 mg TID

inadequate progesterone delivery to the endometrium. This effect may be observed in women who are hypogonadal with long stretches of amenorrhea with lack of E2 stimulation, or after prolonged hormonal replacement with combination estrogen and progesterone. It is probable that prolonged continuous progesterone stimulation of the endometrium produces a profound downregulation of estrogen receptors. These women may all require extended E2 priming to attain an appropriate response prior to progesterone supplementation.

Progesterone is started in the recipient either on the evening of the day of donor oocyte retrieval or 1 day after in order to synchronize endometrial progress with embryo development (Glujovsky et al., 2010). It is generally believed that there is a “threshold level” of serum progesterone that must be achieved for an orderly luteinization of an adequately primed endometrium. However a precise cut off value has not yet been established, though it is commonly accepted to be > 5 ng/mL (Paulson, 2011).

Progesterone, for the purpose of endometrial preparation, is primarily administered by the intramuscular or vaginal routes. Oral progesterone is ineffective because it is rapidly metabolized in the liver. In addition, progesterone is susceptible to metabolism by 5α -reductase in the skin, making transdermal delivery unrealistic due to the large size of the patch that would be required to provide adequate serum levels of the hormone.

Daily intramuscular injections of progesterone produce high luteal phase serum levels of progesterone and reassurance that the progesterone has been appropriately administered. Many programs in the United States still utilize this mode of delivery with a dose of 50–100 mg daily. Even lower doses of 25–50 mg per day results in a secretory endometrium and good pregnancy rates (Tavaniotou et al., 2000).

The advantage of the vaginal route of administration is that the patient does not have to give herself daily injections. Vaginal progesterone has generally been formulated in three ways: micronized progesterone powder encapsulated, a silastic ring which gradually releases progesterone, and a cream formulation. The most frequently used form is the vaginal micronized progesterone inserts which rapidly disintegrate and the released progesterone is absorbed by the vaginal epithelium. Compared to intramuscular administration of progesterone, vaginal progesterone achieves a lower peak serum progesterone levels, but higher endometrial tissue levels, and reaches a steady state in a shorter amount of time (Paulson et al., 2014). Most patients prefer the vaginal route over the pain and inconvenience of daily IM injections (Yanushpolsky et al., 2010).

Oocyte and Embryo Cryopreservation

The ASRM guideline recommends using the age of the egg donor to determine the appropriate number of embryos to transfer (ASRM, 2013a). For donors < 35 years of age the physician and patient should strongly consider elective single embryo transfers (eSET) in an effort to reduce the risk for multiples. The abundant number of oocytes typically retrieved in an oocyte donor cycle and the subsequent surplus embryos may all be cryopreserved as in conventional IVF. Patients may later choose to donate their remaining embryos to an embryo donation program.

The improved cryopreservation technology has also been applied towards commercial “egg banks.” These entities theoretically provide recipients of egg donation with more choices in selecting a donor, extra flexibility in timing, and potentially lower cost. As of 2012, 600 clinical pregnancies were achieved with frozen donor oocytes from seven commercial egg banks identified in the US, with still an estimate of 3130 oocytes from 294 donors stored for future use (Quaas et al., 2013).

Pregnancy and Neonatal Outcomes

Pregnancy and live birth rates after oocyte donation have risen steadily. In the 2015 SART report, fresh donor oocyte cycles achieved a live birth rate of 50.4%, compared to frozen donor oocyte cycles 38.4%. Thawed embryos using donor eggs had a live birth rate of 39.5%, and donated embryos 38.1%.

Oocyte donation cycles were associated with significantly higher rates of multiple gestations (13.9%) compared to women < 35 years using her own eggs (10.6%), and compared to baseline population risk (3%) (CDC, 2012; Kawwass et al., 2013; Kissin et al., 2015). Pregnancy loss after visualization of fetal heart motion has been reported to occur in 5.7% of singleton pregnancies after oocyte donation (Legro et al., 1995). In multiple gestation, the risk of fetal loss appears to positively correlate with the number of gestational sacs, however miscarriage rates (loss of all gestational sacs) do not appear to be increased and most losses occur prior to the 9th week gestation (Rodriguez-Gonzalez et al., 2002). The probability of spontaneous absorption of 1 or more embryos is approximately 19%–28% (Legro et al., 1995; Rodriguez-Gonzalez et al., 2002). Elective multi-fetal reduction from triplets to twins and from twins to singletons have been shown to improve perinatal outcomes in terms of gestational age and birth weight (Haas et al., 2015).

Besides the increased risk of multiples, oocyte donation in itself is an independent risk factor for pregnancy complications, mainly preeclampsia (Table 2) (Malchau et al., 2013). Many studies have shown oocyte donation increases risk for preeclampsia even when controlling for ICSI (Tranquilli et al., 2013), twins (Sekhon et al., 2014), maternal age (Le Ray et al., 2012), and history of chronic hypertension (Levron et al., 2014). One theory is that there is inadequate immunoprotection of the fetoplacental unit (van der Hoorn et al., 2014).

Perinatal mortality and neonatal malformation rates are similar to the general population. A recent study noted good perinatal outcomes in donor oocyte cycles—with pregnancies resulting in term births and low incidences of low birth rate (Kawwass et al.,

2013). Small studies have observed infants conceived after oocyte donation were at higher risk for low birth weight and preterm births (Table 3) (Pados et al., 1994; Abdalla et al., 1998; Soderstrom-Anttila et al., 1998b; Sheffer-Mimouni et al., 2002) however after controlling for preeclampsia, neonatal outcomes were similar between oocyte donation cycles and traditional IVF (Malchau et al., 2013; van Dorp et al., 2014). In a 5 year follow-up study of children conceived with oocyte donation, all were healthy with similar growth and developmental rates to children in the general population (Soderstrom-Anttila et al., 1998a).

Advanced Reproductive Age

Even in women over the age of 50, pregnancies can be achieved using donor oocytes and with the appropriate endometrial preparation (Sauer et al., 1993b,c). However with the ability to facilitate pregnancies in the advanced maternal age, medical, and ethical concerns should also be addressed. Precycle screening of women of advanced reproductive age should comprise a thorough medical and physical evaluation including a cardiovascular stress testing (Table 4). All recipients, particularly menopausal women, should also undergo a practice hormone replacement cycle with an endometrial biopsy to confirm adequate estrogen priming and subsequent luteinization of the endometrium.

Large studies on obstetrical and perinatal outcomes in the very advanced maternal age are limited. While some studies noted higher incidences of gestational diabetes, preeclampsia, and cesarean section rates in this older age group (Table 5) (Kort et al., 2012; Jackson et al., 2015) other studies have also noted similar obstetrical risk between donor oocyte recipients in advanced maternal age and younger recipients (Krieg et al., 2008; Kort et al., 2012). In one study of 77 postmenopausal women 50 years or older using donated eggs, pregnancy rates, multiple gestation rates, and spontaneous abortion rates were similar to those of younger recipients (Paulson et al., 2002). In another recent study, subanalysis comparing women ≥ 45 years who conceived via donor oocyte or autologous IVF cycles, both groups had similar rates of postpartum hemorrhage, cesarean section, gestational age, and birth weights (Jackson et al., 2015). Therefore it appears that oocyte donation in itself does not further increase obstetrical or perinatal risks in advanced maternal age women.

Table 4 Screening tests for prospective recipients of oocyte donation over the age of 45 years

^aGestational hypertension 10.8%.^bGestational hypertension 11.8%.^cInclusive of all hypertensive disorders.

Support for egg and embryo donation in postmenopausal women have expounded on the greater gender equality and reproductive freedom. Counter-arguments have focused on the psychologic impact on the children and concerns regarding the physical and parenting capabilities of these older parents (Shufaro and Schenker, 2014). In a study comparing parenting stress and physical functioning in women who conceived after the age of 50 compared to women in their 30s, advanced maternal age was not found to reduced parenting capacity (Steiner and Paulson, 2007).

The ASRM ethics committee has indicated it is reasonable to offer oocyte and embryo donation services for appropriately screened patients between the ages of 50 and 54 years without any persistent psychological, medical or obstetrical concerns (ASRM, 2013b).

Summary

Oocyte donation, designed to overcome blocks to fertility caused by oocyte problems is a logical extension of the technology of IVF. Additionally, embryo donation is a practical option for couples with female and male factor infertility who may need both egg and sperm donation. Stimulation of the oocyte donor is similar to standard IVF, yet may be less complicated, since poor responder protocols are rarely needed, and concerns about hyperstimulation are essentially eliminated with an antagonist protocol with gonadotropin agonist trigger. Preparation of the recipient endometrium and synchronization between oocyte donor and recipient

are also achieved with relative ease. Recipients of cryopreserved embryo donation are even simpler, requiring only endometrial preparation without need for coordination with the donors. Donors as well as recipients should be medically screened and offered psychosocial counseling to address issues of third-party parenting. Since oocyte and embryo donation bypasses most age-related block to conception in women of advanced reproductive age, it is possible to establish pregnancies in menopausal women over 50 years of age. Perinatal outcomes after oocyte donation appear similar to those after traditional assisted reproductive technologies, with a possible increase in the incidence of hypertensive disorders of pregnancy.

SEMEN ANALYSIS

Understanding Bulk Seminal Parameters

Grace M Centola, Reproductive Laboratory and Tissue Bank Consultant, Port St. Lucie, FL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Although the semen analysis is not a test of actual fertility, it provides the clinician with ample information to determine if there is a male factor affecting the inability of the couple to conceive. The routine semen analysis is an accurate measurement of sperm production and maturation, and the ejaculatory process (Centola, 1996; Lewis, 2007; Sikka and Hellstrom, 2016). Sperm fertility, that is., ability to fertilize an egg and subsequent processes, cannot be established by a routine semen analysis, and therefore more advanced tests often must be used to determine actual fertility (Lewis, 2007; Sikka and Hellstrom, 2016). The physician interprets the qualitative and quantitative semen analysis results and determines if further testing is warranted.

There is large biological variation in semen quality which is generally uncontrollable, and explains the individual variations seen between and within males (Keel, 2006; Castilla et al., 2006; WHO, 2010). A minimum of two semen analyses should be done to account for variation within individuals and between specimens.

A third analysis might be necessary if the previous analyses show different results.

It is important that the specimen be collected properly, methods standardized and results properly interpreted (Sigman et al., 2009; Poch and Sigman, 2010; Bjorndahl et al., 2010; Centola, 2011). Each lab report should list the normal or reference ranges, which will assist the physician with interpretation of the results. The normal range is obtained from published standards (such as WHO, 1999 or WHO, 2010), or an intra-laboratory range established by analysis of a local population of fertile men with pregnant partners (Bjorndahl, 2010; Niederberger, 2011).

Threshold values for sperm concentration, motility and morphology can classify the male as fertile or subfertile, or of indeterminate fertility (Guzick et al., 2001). The only way to determine that sperm are able to fertilize an egg is through in vitro fertilization or a current pregnancy.

Interpretation and Understanding of Bulk Seminal Parameters

The abstinence period, the method of collection and the time from collection to analysis will influence the results of the semen analysis. Therefore, specific instructions are provided to minimize inaccurate results. It is important that instructions are followed, and the laboratory is informed of any nonconformances since these may affect the results and invalidate the analysis.

The entire ejaculate should be collected into an aseptic or sterile specimen container provided by the laboratory. It is preferable to collect in a private room provided at the laboratory facility. However, if this is not possible, a specimen can be collected off-site provided that the specimen can be maintained at body temperature and delivered to the laboratory within 30–45 min of ejaculation. Coitus interruptus is not a reliable means to collect a specimen for analysis since the first part of the ejaculate is easily lost, and there may be cells and bacteria from the vaginal fluid contaminating the semen specimen (WHO, 2010). Over the counter latex condoms should not be used since they contain toxic chemicals that interfere with sperm motility (Jones et al., 1986; WHO, 2010).

If any portion of the ejaculate is lost or not collected, it should be reported to the laboratory performing the test (WHO, 2010). The first part of the ejaculate is the sperm-rich fluid, and therefore loss of this part will influence the results. If the sperm are kept in the raw ejaculate for an extended time, motility may decrease, and thus the time of collection and time of analysis are important to interpretation of the results.

A 2–3 day period from the last ejaculation is a standard abstinence time. Others have suggested an abstinence time of 2–7 days (WHO, 2010). It is not better to have a longer abstinence thinking that a longer time is better. A prolonged abstinence may cause increased numbers of dead, dying and nonmotile sperm (Centola, 2011).

Liquefaction and Viscosity

Upon collection, the semen is coagulated as a result of proteins from the seminal vesicles (Rothman and Reese, 2009; Turner, 2009; Bjorndahl et al., 2010). Between 30 and 45 min after specimen collection, and usually within 15–20 min, the semen liquefies due to enzymes present in the semen from the prostate gland (Rothman and Reese, 2009; Turner, 2009; Bjorndahl et al., 2010). With liquefaction, the ejaculate becomes thinner, more liquid and watery. If the ejaculate does not properly liquefy, abnormalities, including inflammation or infection of the accessory sex glands should be considered (Turner, 2009; Bjorndahl et al., 2010). Loss of part of the ejaculate, and hence loss of the fluid contributed by the seminal vesicles or prostate gland can also result in abnormal liquefaction.

Decreased motility may result from incomplete liquefaction (Rothman and Reese, 2009). Lack of, or partial liquefaction can also impair contact of the ejaculate and the sperm with the female's cervix following coitus.

Viscosity is the consistency or fluidity of the ejaculate. It is important to note that determining viscosity is very different from determining liquefaction. If the semen demonstrates discreet droplets when expelled from a disposable pipette, the viscosity is considered normal. However, if the semen does not form discreet droplets, falling thick and stringy from a pipette, there is increased viscosity. High viscosity can interfere with accurate semen analysis. Motility may also be reduced by increased viscosity. If the semen is viscous, the sperm will not make effective contact with the cervix. Although not the same as formation of a coagulum and liquefaction, viscosity can be related to disturbed accessory gland function, including inflammation and infection (Bjorndahl et al., 2010). Increased viscosity can also be related to dehydration or lack of fluid intake. Additional semen analyses and further evaluation may be warranted to determine if the increased viscosity is an isolated finding or persistent.

Color

A normal ejaculate appears as gray to white and opaque. A clear ejaculate may indicate a reduced sperm concentration, or azoospermia (Centola, 2011). Abnormal color may indicate the presence of red blood cells (pink or red-brown in color) (WHO, 2010). The presence of red blood cells may simply be due to skin abrasion during collection or an infection of one of the accessory sex glands (Bjorndahl et al., 2010). Infection, jaundice or vitamins and certain drugs may result in a yellow-colored semen (WHO, 2010). A yellowish color can also be related to prolonged abstinence (Bjorndahl et al., 2010). An unpleasant odor might also be related to infection or extended storage (age) of the specimen before lab analysis. Similarly, additional semen analyses and further evaluation may be warranted to determine if this is an isolated finding.

Volume and pH

The fluid making up the ejaculate is contributed by the accessory sex glands, primarily the prostate gland, which contributes 20%, the seminal vesicles, which contributes 70%, and a small portion from the bulbourethral glands and epididymis (Bjorndahl et al., 2010; WHO, 2010). Approximately 10% of the ejaculate volume is contributed by the testicles. The seminal vesicles provide alkaline fluid, while the prostate gland provides acidic fluid (Oates, 2012). The normal reference range for semen volume is 1.5–6.0 mL (WHO, 2010).

Clinical relevance becomes apparent only when the semen volume is equal to or less than 1.0 mL (Niederberger, 2011). Low semen volume can indicate dysfunction of the accessory sex glands (i.e., seminal vesicles, prostate), ejaculatory duct blockage, congenital absence of the vas deferens, or incomplete collection of the specimen (Poch and Sigman, 2010; WHO, 2010; Centola, 2011; Niederberger, 2011). Stress during collection or ejaculatory failure may also affect semen volume (Bjorndahl et al., 2010). Retrograde ejaculation, which occurs when the semen passes into the bladder rather than outward through the urethra, could result in low ejaculate volume or no antegrade ejaculation and thus no semen (Poch and Sigman, 2010; Niederberger, 2011).

High volume is often seen in inflammation or infection of the accessory glands, particularly the prostate (Bjorndahl et al., 2010; WHO, 2010). High volume results in dilution of the sperm, resulting in a lower concentration (million per milliliter). High volume can also result in impaired contact with the cervix and loss of the ejaculate from the vagina. Low semen volume may result in the spermatozoa being impaired by the acidic vaginal environment and poor contact with the cervix. Reduced contact with the cervix and loss of semen from the vagina can also occur with high semen volume (Bjorndahl, 2010).

The semen pH reflects the balance between the secretions from the seminal vesicles and prostate gland (WHO, 2010). In cases of azoospermia, pH may point towards accessory gland dysfunction (Rothmann and Reese, 2009). Low volume and low pH with no sperm usually indicates obstruction or absence of the vas deferens (Sikka and Hellstrom, 2016; Oates, 2012). Semen pH increases over time and with exposure to ambient air (Rothman and Reese, 2009; WHO, 2010). Thus, pH might have little useful information especially if the volume, concentration and motility are close to or within normal limits. Currently, most semen analyses do not include measurement of pH.

Concentration and Motility

Concentration and motility are probably the most important of the bulk seminal parameters. The term oligozoospermia refers to low sperm count and asthenozoospermia refers to reduced motility. Cryptozoospermia refers to sperm counts that are so low as to be nearly azoospermic (Niederberger, 2011).

The sperm concentration, or sperm density, refers to the numbers of sperm per unit of volume (milliliter) of semen. The total sperm count, which is the concentration times the semen volume, is thought to be more relevant than sperm concentration (Rothmann and Reese, 2009). The total count (number of spermatozoa per ejaculate) provides a measure of testicular function and the patency of the ejaculatory tubules (Rothmann and Reese, 2009; WHO, 2010). The total motile count (often referred to as TOMO) is also an important and relevant measurement, taking into consideration the sperm concentration, motility and semen volume. The lower reference limit for sperm concentration is 15 million sperm per milliliter (range 12–16) (WHO, 2010). The reference value for total sperm count is 39 million (WHO, 2010). The thresholds for sperm concentration were previously reported as 13.5 million/mL and 48 million/mL (Guzick et al., 2001), which means that in men with a sperm concentration greater than the threshold, any medical or surgical treatment is unlikely to significantly increase the odds of conception (Niederberger, 2011). Pregnancy rates

will be decreased if sperm counts are below the reference values of 15–20 million per milliliter, but only below 5 million per milliliter will fertility be significantly reduced (Bjorndahl, 2010; Poch and Sigman, 2010; Niederberger, 2011).

Besides incomplete sample collection, sperm count can be affected by abstinence time, and external factors such as general illness and fever, medications, recreational drug use and environmental or occupational exposures (Bjorndahl et al., 2010). Low sperm count can be caused by hormonal problems. Elevated FSH hormone with low sperm count can indicate testicular failure. Chromosome microdeletions, specifically Y-chromosome deletions, should also be considered as causative of severely low sperm count or azoospermia (Oates and Lamb, 2009; Niederberger, 2011).

Sperm motility is more difficult to assess than sperm numbers, since motility can be highly subjective. Furthermore, motility is often inaccurately reported by labs which infrequently perform semen analyses, and by technicians unfamiliar with the appearance of motile sperm under a microscope (Niederberger, 2011). The sperm motility is usually reported as total percent motility. A classification of progressive motility, that is movement that is rapid and mostly in a linear pattern can also be helpful to interpretation. Rapid progressive motility is an important functional property of sperm related to fertility and fertilization success (Bjorndahl et al., 2010). The WHO classifies motility as “progressive motility” where sperm are actively moving either linearly or in a large circle regardless of speed, “nonprogressive motility” which includes all other patterns of movement where the sperm move but do not progress, and no motility or movement at all (WHO, 2010; Niederberger, 2011). The classification of the total motility reported by the laboratory should be defined on the lab report. Usually, the total motility includes both progressive and nonprogressive motility, and is calculated as the number of motile sperm divided by the total number counted, expressed as percent. Along with progressive and nonprogressive motility, the quality of sperm movement is often classified according to a number scale (0–4) or letter scale (type a to d). The lower reference limit for total motility is 40% and for progressive motility is 32% (WHO, 2010). The fertility thresholds have been reported between 32% and 63% (Guzick et al., 2001).

Sperm motility is affected by many factors, including but not limited to the length of holding time from collection to analysis, and medical factors, such as presence of a varicocele, exposure of the testes to increased temperature and environmental exposures. A varicocele is an enlargement or dilatation of the veins of the testicles (Nagler and Grotas, 2009). Low motility may also be caused by prolonged abstinence, genital infection and inflammation of the accessory sex glands, antisperm antibodies and sperm structural defects (Sigman et al., 2009; Bjorndahl et al., 2010; Niederberger, 2011). Complete absence of motility can be caused by ultrastructural defects in the sperm midpiece or tail, a condition referred to as immotile cilia syndrome or Kartagener’s syndrome (Sigman et al., 2009; Bjorndahl et al., 2010).

Vitality or viability assessment can be a check on accuracy of low motility measurement, and allows the lab to distinguish complete immobility due to defects in the sperm midpiece or tail and other factors (Mortimer, 1994; Bjorndahl, 2010). In cases of low motility, especially in samples with less than 40% motility (WHO, 2010) (some laboratories use less than 25% as a threshold to perform a viability stain), a stain can be used to determine if the nonmotile sperm are metabolically alive. Sperm that have damaged membranes, and are thus dead, will take up the vital stain. The total number of live sperm by dye exclusion is obtained by multiplying the percentage of live sperm by the total sperm count.

In such cases, the reduced viability might be due to factors such as toxic exposure, exposure to temperature extremes, antisperm antibodies or structural defects (Sigman et al., 2009; Bjorndahl, 2010). A high percentage of live but immotile sperm may indicate structural defects, but a high percentage of immotile and nonviable sperm may indicate testicular (epididymal) dysfunction (WHO, 2010).

Morphology

Assessment of sperm morphology remains an important part of the routine semen analysis. The term, teratozoospermia refers to increased abnormal sperm forms. While some report sperm morphology as predictive of outcome in assisted reproduction (Kruger et al., 1988), others question its relevance (Centola, 1996, 2011; Centola and Jeyendran, 2009; Rothman and Reese, 2009; Bjorndahl, 2010), specifically because of the wide variations in morphology assessment between laboratories. Two types of morphology classification have been used, a strict morphology also referred to as “Kruger” morphology, and a less strict method referred to as WHO morphology (Kruger et al., 1988; WHO, 1999; Niederberger, 2011). The most recent version of the WHO manual endorsed a stricter method of classification (WHO, 2010; Niederberger, 2011).

A normal sperm is defined as one with a smooth, oval head and a clearly visible acrosomal cap. The sperm tail is 45–50 μm long with no breaks or sharp bends (Bjorndahl et al., 2010; WHO, 2010). Sperm defects are classified as head, midpiece and tail defects. Head defects include small or large head, elongated or tapered head, acrosomal defects, duplicate heads and amorphous heads, which are those with defects not falling into the previously indicated categories. Midpiece defects include bent necks, thick or thin necks, or if there is off-center insertion of the tail into the midpiece. Tail defects include bent tails (bent at any area along the tail length), short tails, coiling of the tail or coiled tips of the tail. In rare cases, all sperm can show giant heads, pin heads or uniformly round heads with no acrosomal cap (Niederberger, 2011). In the case of absent acrosomes, assisted reproduction, particularly ICSI is the only treatment.

Using the strict method of classification, any abnormality even if considered borderline normal versus abnormal, is classified as abnormal. The previous less strict method would classify such a sperm as normal. The current reference value for normal morphology is 4% (WHO, 2010). The thresholds for normal morphology have been reported as 9% and 12% normal forms (Guzick et al., 2001).

The majority of cases of increased abnormal sperm have no medical explanation. However, varicocele, extremes in temperature and, infrequently, genetic defects can cause sperm morphological defects (Oates and Lamb, 2009; Nagler and Grotas, 2009; Niederberger, 2011). Toxic and environmental exposure can also cause morphological defects (Katz, 1991; Rothmann and Reese, 2009). For example, increased tapered sperm heads may be a result of varicocele, duplicate heads, round heads or pin-headed sperm might be related to testicular trauma, toxic exposure or genetic defects (Katz, 1991; Nagler and Grotas, 2009; Oates and Lamb, 2009; Poch and Sigman, 2010; Niederberger, 2011). The percentage of abnormal sperm and the type of abnormalities can assist the physician in determining a treatment regimen for the infertile couple (Centola and Jeyendran, 2009). Even in cases of severe teratozoospermia, fertilization is possible (Poch and Sigman, 2010), although pregnancy rates in these cases are low even with assisted reproductive procedures (Sigman et al., 2009). It is important to remember that consistent high percentage of abnormal forms can be clinically significant, whereas isolated increased abnormal forms without other abnormal parameters are probably clinically insignificant (Niederberger, 2011).

Conclusion

A thorough history and physical exam, and multiple semen analyses will assist the physician in determining if further testing, such as hormone or genetic testing is needed. The physician will determine if medical or surgical intervention might increase the fertility potential of the male. Together with information from evaluation of the female partner, male evaluation will direct the clinician to an individualized treatment plan for the couple. Options might also include assisted reproductive procedures such as artificial insemination, and IVF/ICSI.

Laboratory Evaluation of Bulk Seminal Parameters

Grace M Centola, Reproductive Laboratory and Tissue Bank Consultant, Port St. Lucie, FL, United States

Introduction

The semen analysis is the initial test for evaluation of the male partner. It is an important test which provides the clinician with useful information on the fertility potential of the male partner, but is not a test of fertility (Centola, 1996, 2011). The routine semen analysis is an accurate measurement of sperm production and maturation, and the ejaculatory process (Centola, 1996; Lewis, 2007; Sikka and Hellstrom, 2016). Sperm fertility, that is, ability to fertilize an egg and subsequent processes cannot be established by a routine semen analysis, and therefore more advanced tests must be used to determine fertility potential (Lewis, 2007; Sikka and Hellstrom, 2016). A semen analysis should be performed by an andrology laboratory, which specializes in semen analysis and advanced sperm testing. The basic techniques of semen analysis established over 50 years ago are still used for routine practice (Pacey, 2012). Most recently home sperm analysis kits, which provide information on the presence of sperm in the ejaculate, are available at most independent pharmacies.

A minimum of two separate specimens, provided at appropriate intervals should be analyzed to account for inherent specimen variation (WHO, 1999, 2010; Poch and Sigman, 2010; Sigman et al., 2009). There is large biological variation in semen quality which is largely uncontrollable, and explains the individual variations seen between and within males (Keel, 2006; Castilla et al., 2006; WHO, 2010). Method of collection, abstinence period, and circumstances of delivery to the laboratory are important for the laboratory results to be accurate and reliable (Centola, 1996, 2011; Bjorndahl, 2010; Bjorndahl et al., 2010; Sigman et al., 2009). Standardized methods for semen analysis are part of good laboratory practice and include quality control, proficiency testing, and technician competency evaluations (Castilla et al., 2006; Bjorndahl, 2010; Drobnis, 2016).

Laboratory Evaluation

The results of semen analyses are influenced by many factors. The clinical laboratory must provide specific instructions regarding abstinence period, method of collection, and holding temperature to minimize inaccurate analyses. It is extremely important that the specimen be collected properly, methods standardized, and results properly interpreted (Sigman et al., 2009; Bjorndahl et al., 2010; Centola, 2011; Agarwal et al., 2016a). The entire ejaculate should be collected into an aseptic or sterile specimen container provided by the laboratory. If any portion of the ejaculate is lost or not collected, it should be reported to the laboratory technician (WHO, 2010). The first part of the ejaculate is the sperm-rich part of the specimen; therefore, loss of this part will influence the results. Generally, 2–3 days abstinence from the last ejaculation is a standard abstinence time. Others have suggested an abstinence time of 2–7 days (WHO, 2010). Each laboratory must provide information regarding abstinence period in addition to method of collection. In most cases, a longer abstinence period may result in increased numbers of dead, dying, and nonmotile sperm, thus not an accurate picture of semen quality (Centola, 2011).

Specimens are collected using masturbation in a private room at the laboratory facility (Sigman et al., 2009; WHO, 2010). If a specimen can be delivered to the laboratory within a specified timeframe, a specimen can be produced off-site. Special nontoxic condoms might also be used by those who are not able to collect by masturbation (Sigman et al., 2009; Poch and Sigman, 2010). These condoms are available commercially or at some andrology laboratories. Ordinary latex condoms should not be used since they contain toxic chemicals that interfere with sperm motility (Jones et al., 1986; WHO, 2010). Coitus interruptus is not a reliable means to collect a specimen for analysis since the first part of the ejaculate is easily lost, and there may be cells and bacteria from the vaginal fluid contaminating the semen specimen (WHO, 2010).

If collected off site, the specimen must be delivered within 30–45 min of ejaculation. Specimens should be maintained at body temperature (preferably) or room temperature during transport to the laboratory. The specimen should not be exposed to extreme temperatures which will affect sperm motility (WHO, 2010). Upon receipt, the technician will place the properly labeled specimen container in a 37°C incubator or at room temperature until analysis.

Upon collection, the semen is a coagulated mass, but with time (usually within a maximum of 30–45 min post collection), the semen liquefies, becomes thinner, more liquid and watery (WHO, 2010). Liquefaction is facilitated by gentle mixing of the specimen container. The laboratory should note if the specimen is not completely liquefied by 1 h after collection. The semen analysis should begin soon after liquefaction, preferably 30 min after collection but not longer than 60 min to prevent decrease in sperm motility with prolonged exposure to the seminal fluid (WHO, 2010).

If the semen specimen remains as a coagulated mass by 1 h after collection, the laboratory can add buffered medium, perform repeated mixing or passage through a large bore syringe. Treatment with an enzyme such as bromelain dissolves the coagulum but may affect results (WHO, 2010). Such methods, and if effective or not, should be recorded on the laboratory report. The presence of gelatinous granules in the liquefied semen does not appear to have any clinical significance, although mucus strands may interfere with the analysis (WHO, 2010).

Initial Assessment

Semen consistency

Following liquefaction, the semen sample is aspirated into a wide-bore disposable pipette to determine the consistency or viscosity of the ejaculate. It is important to note that determining viscosity is very different from determining liquefaction. The semen is drawn into the disposable pipette and allowed to drop out of the pipette back into the container. If the sample demonstrates discreet drops, the viscosity is considered normal. However, if the semen does not form discreet droplets, falling as thick and stringy, there is increased viscosity. The viscosity can be rated on a scale (0 = normal to 4 = extremely viscous), or by using qualitative terms, such as normal, moderate, extreme. A viscous specimen interferes with accurate analysis of motility and concentration, but most importantly can inhibit contact with, and transport through, the female reproductive tract.

Semen color

The normal ejaculate appears as gray to white and opaque. A clear ejaculate may indicate a reduced sperm concentration or azoospermia (Centola, 2011). The presence of red blood cells will cause the semen to appear red-brown or pink. Bacterial infection may cause the semen to appear green or yellow, and certain medications or vitamins may also turn the semen a yellow color (WHO, 2010; Centola, 2011). The next steps in the semen analysis are the measurement of the semen volume or amount, the sperm count, motility, and normal forms or morphology.

Semen volume

The fluid of the ejaculate is contributed by the accessory sex glands, primarily the prostate gland and the seminal vesicles, with a small amount from the bulbourethral glands and epididymus (Bjorndahl et al., 2010; WHO, 2010). Approximately 10% of the ejaculate volume is contributed by the testicles, 70% by the seminal vesicles, and 20% from the prostate gland. The seminal vesicles provide alkaline fluid, while the prostate gland provides acidic fluid (Oates, 2012). The semen volume is measured by pipetting the semen into a graduated serological pipette (Rothmann and Reese, 2009; Bjorndahl, 2010) or use of other types of laboratory measuring devices such as graduated cylinders or graduated centrifugation tubes (Bjorndahl, 2010). Due to inherent inaccuracies with such methods, obtaining a weight of both the empty specimen container and the container with semen is considered by some to be a preferred method to determine volume (Bjorndahl, 2010; WHO, 2010). The density of the semen is consistent at 1 g/mL; therefore, the weight of the empty container is subtracted from the (heavier) weight of the container with semen, resulting in the semen volume (WHO, 2010). The lower reference limit for semen volume is 1.5 mL (1.4–1.7) (WHO, 2010); others report a range of 1.5–6.0 mL (Sikka and Hellstrom, 2009).

Semen pH

Measurement of semen pH is no longer routinely performed, particularly if sperm are present (Rothmann and Reese, 2009; Centola, 2011; Oates, 2012). Semen pH varies with time after ejaculation and exposure to ambient air. Therefore, if performed, the pH should be measured as soon as possible after liquefaction. The lower reference value for semen pH is 7.2 (WHO, 2010).

Microscopic Assessment

Following the above measurements, the semen is thoroughly mixed by swirling of the specimen cup and/or drawing into and expelling out of a disposable pipette. A drop of semen is placed on a clean glass slide and covered with a thin glass coverslip. The slide is examined for the presence of sperm agglutination or clumping, bacteria, and the presence of other types of cells such as round cells and white blood cells (Rothmann and Reese, 2009; Bjorndahl, 2010; WHO, 2010; Agarwal et al., 2016a,b,c). The type of round cells can be classified by examining a stained slide (WHO, 2010).

Sperm motility and sperm concentration

Sperm concentration refers to the number of sperm per unit volume (milliliter) of semen and the total sperm count is the total number of sperm in the entire ejaculate (sperm concentration times semen volume) (Sigman et al., 2009; WHO, 2010). Sperm concentration is determined using specialized counting chambers such as the improved Neubauer hemocytometer, a Makler chamber, or disposable slide chambers (Mortimer, 1994; Centola, 2011; Bjorndahl, 2010; WHO, 2010; Agarwal et al., 2016a). The hemocytometer was used for many years to determine sperm count and still is used in many hospital laboratories. The hemocytometer, however, required that an aliquot of the semen be fixed so that the total number of sperm can be counted. The need for performing these counts in duplicate requires additional labor and time to clean and load the chamber, introducing variations, and errors (Rothmann and Reese, 2009).

Specialized chambers for determining sperm count have been developed and are routinely used in the andrology laboratory. The counting chambers do not require dilution and have a depth appropriate for sperm allowing determination of motile and nonmotile sperm on the same chamber (Rothmann and Reese, 2009; Sikka and Hellstrom, 2016). The disposable slides have two built-in chambers for replicate counts (Seaman et al., 1996; Brazil et al., 2004; Agarwal et al., 2016a,b,c). The Makler chamber is a reusable chamber for concurrent measurement of sperm count and motility (Makler, 1980; Seaman et al., 1996). The Makler chamber requires precise specimen loading and handling and is cleaned following each use. The numbers of motile and nonmotile sperm are recorded within the boundaries of the slide grid, and the count and motility calculated.

A minimum of 200 spermatozoa should be counted, although for low count specimens, counting of 100 sperm may be used. Highly concentrated specimens need dilution to accurately determine the sperm count and motility. However, with experienced technicians, the count and motility can be estimated, and this might be sufficient for the clinician to formulate a treatment plan. A report of “greater than 50 or 100 million sperm” might be acceptable to the clinician.

Determination of accurate sperm count in specimens with severely low concentration can be inaccurate and potentially misleading. In such specimens, a standard reporting of “< 1 million sperm/mL” can be used, with notation of percent and quality of motility. When few, rare or no spermatozoa are seen on a wet mount slide, the specimen should be centrifuged to determine if any sperm are present (WHO, 2010). In these cases, a report might indicate “few sperm seen,” or “1 per high power field,” for example, which may be enough information for the clinician to formulate a plan.

There are advantages and disadvantages to the sperm counting chambers. However, it is important to validate any chamber the laboratory chooses to use and to perform daily quality control for each chamber type. Significant variability between chambers has been reported, emphasizing the need for laboratory standardization and quality control (Seaman et al., 1996; Rothmann and Reese, 2009).

The lower reference limit for sperm concentration is 15 million sperm per milliliter (range 12–16) (WHO, 2010).

Sperm motility should be evaluated immediately after semen liquefaction, usually within 30–45 min of ejaculation (WHO, 2010). The semen specimen is mixed well, and a drop is immediately removed and placed on a clean glass slide. If the disposable or Makler chamber is used, the chamber is loaded and both the sperm count and motility can be concurrently determined (see above). The numbers of motile sperm and the numbers of nonmotile sperm are counted out of at least 200 sperm (Bjorndahl, 2010; WHO, 2010; Agarwal et al., 2016a,b,c). The percentage motility is determined by dividing the number of motile sperm by the total number (motile + nonmotile) counted, times 100%.

To account for sampling errors and heterogeneity of the sample, the sperm motility and the sperm count should be determined in separate duplicate samples on two different slides (Bjorndahl, 2010; Sikka and Hellstrom, 2016). If the replicates are >10% different, a third slide should be examined. The most difficult part is to determine the moving sperm especially in a high count specimen. Laboratory technicians are rigorously trained to recognize the motile sperm and to count each sperm only once which can be difficult when motile sperm are rapidly moving all over the microscopic field.

Motility is assessed in four categories—nonmotile, motile but nonprogressive, slowly progressive, and rapidly progressive (Mortimer, 1994; Bjorndahl, 2010; WHO, 2010; Sikka and Hellstrom, 2016). Progressive motility is defined as progressive movement usually in a linear direction (straight progression) or in a large circle, regardless of speed of progression (WHO, 2010). Motile but nonprogressive movement is seen with slow, sluggish, or weak forward movement (Mortimer, 1994). Rapid progression is defined as those sperm moving in a rapid linear movement. Different number (0–4) or letter (a–d) scales may be used by laboratories to determine the quality of the movement in each category, although this is difficult to define accurately without bias (Mortimer, 1994; WHO, 2010). After counting all motile sperm in each category, the percentages of each can be determined. The total percent motility with a motility scale and the sperm count are then reported.

The lower reference limit for total motility is 40% and for progressive motility is 32% (WHO, 2010).

Sperm vitality or viability

Sperm vitality or viability is an assessment of the live versus dead sperm based on a dye exclusion method. In a specimen that shows a good motility, the assumption is made that the motile sperm are viable (Bjorndahl, 2010), and performing a vitality stain might not be necessary.

The live/dead staining is important to be performed for specimens that present with <40% progressively motile sperm (WHO, 2010). In such a specimen, the question arises if the nonmotile sperm are alive, but not motile, and could potentially be used for assisted reproduction. Vitality assessment is also a check on accuracy of motility measurement, and allows the lab to distinguish complete immobility due to defects in the sperm midpiece or tail (Mortimer, 1994; Bjorndahl, 2010). Vitality is assessed using a dye exclusion method, where the live sperm with intact membranes do not take up the dye and the dead sperm with damaged membranes take up the stain (Mortimer, 1994; Bjorndahl, 2010; WHO, 2010). Live cells can be assessed using several vital dyes, which include eosin Y, trypan blue, or a fluorochrome Hoeschst 33258 (Mortimer, 1994; WHO, 2010). The most commonly used technique is the eosin staining method, which includes a counterstain, nigrosin, which allows an easier way to distinguish the background and the sperm heads (WHO, 2010; Agarwal et al., 2016c).

After the specimen is mixed, a small amount is removed, and mixed with the stain in a small test tube. After mixing, a drop is smeared on a clean glass slide and allowed to air dry. The cells stained pink are dead, and the unstained clear cells are live cells. Replicate slides are prepared and assessed, and the mean is reported as percent live sperm.

A second, less common routine vitality test is the hypoosmotic swelling (HOS) test, which assesses the ability of the sperm cells to swell in a special hypoosmotic buffer (Mortimer, 1994). The HOS test is especially helpful when choosing sperm for ICSI because no toxic stain or fixative is used (WHO, 2010). When sperm are mixed with the hypoosmotic buffer, those with intact membranes show swelling in the tail and midpiece sections (WHO, 2010).

The lower reference limit for vitality using either method is 58% (range 55–63) (WHO, 2010).

Sperm morphology

Assessment of sperm morphology remains an important part of the routine semen analysis. While some report sperm morphology as predictive of outcome in assisted reproduction, others question its relevance (Centola, 1996, 2011; Centola and Jeyendran, 2009;

Rothmann and Reese, 2009; Bjorndahl, 2010). The percentage of abnormal sperm and the abnormalities can assist the physician in determining a treatment regimen for the infertile couple (Centola and Jeyendran, 2009).

Sperm morphology is one of the most confusing and difficult parts of the semen analysis (Rothmann and Reese, 2009; Bjorndahl, 2010; Sikka and Hellstrom, 2016). There are many factors which contribute to this confusion, including but not limited to variation between laboratories, variation between technicians within a lab, multiple classification methods, multiple slide preparation and staining methods, not to mention the variability in the sperm cells themselves.

A number of stains have been used to prepare a morphology slide, including the Papanicolaou stain, Wright-Giemsa, and Diff-Quick stains, some of which are sold in kit form (Mortimer, 1994; Centola, 2011; Centola and Jeyendran, 2009; Bjorndahl, 2010; Rothmann and Reese, 2009; WHO, 2010; Agarwal et al., 2016b). An accurate morphology cannot be obtained using an unstained wet mount slide (Centola and Jeyendran, 2009). By preparing a stained slide of a semen smear, the structure of the sperm cells can be observed under the microscope. A simple normal or abnormal classification with optional tally of the types of abnormalities is the most recommended method of determining sperm morphology (WHO, 2010).

Several classification methodologies are used to determine morphology. These include the WHO methods (WHO, 1999, 2010) and Strict methods (Menkveld et al., 1990; Kruger et al., 1988; Kruger and Franken, 2004; Agarwal et al., 2016b).

A minimum of 100 sperm are observed at high magnification on a stained slide. Only sperm with a tail are counted. The technician then rates each sperm cell as normal or abnormal. Most types of abnormal sperm are easily recognized, the difficulty arises in deciding that a normal appearing sperm cell is actually normal. Each sperm cell must show a uniform, smooth, and oval head; a regular and slender midpiece; and a thin tail which is estimated at 10 times the head length (WHO, 2010). Defective sperm include large, small, tapered or irregularly shaped head; bent or thin midpiece; and short, broken, coiled, or multiple tails.

The strict classification of sperm morphology uses stricter criteria to determine a normal sperm. A microscope eyepiece reticle is used to measure the head, midpiece, and tail. Each part of the sperm must be uniform and precise in size, with no defects. A normal sperm is one which conforms to four strict criteria (Kruger et al., 1988; Kruger and Franken, 2004; Centola and Jeyendran, 2009; Agarwal et al., 2016b). Any sperm cells not conforming to the four criteria, including borderline or questionable, are classified as abnormal when using strict criteria. Earlier versions of the WHO manual classified borderline as normal, while later versions classified such as abnormal (WHO, 1999, 2010).

It takes significant training and experience to reliably assess sperm morphology in an accurate and reproducible way. The normal reference value for sperm morphology is 4% (range 3.0–4.0) (WHO, 2010). Strict criteria reference ranges are as follows: <4% normal, severely impaired function; 4%–14% normal, questionably impaired; > 14% normal, potentially normal fertility (Kruger et al., 1988; Kruger and Franken, 2004; Centola and Jeyendran, 2009; Agarwal et al., 2016b).

Conclusion

Routine semen analysis provides significant information to the clinician managing the infertile couple. Information on sperm production and maturation, including morphology, allow the physician to potentially diagnose the cause of infertility or at least request additional testing of both partners. Andrology testing is classified as high complexity testing and requires trained staff with appropriate education (Drobnis, 2016). In order for a laboratory to provide reliable and precise information, each lab must establish and validate the methodology used and participate in proficiency testing to insure all staff are proficient in these methods. Furthermore, laboratory state and federal licensing, and, internal quality assurance, and improvement processes are essential (Centola, 2016).

CASA—Computer-Aided Sperm Analysis

Sharon T Mortimer, Oozoa Biomedical, West Vancouver, BC, Canada
Christopher J De Jonge, University of Minnesota, Minneapolis, MN, USA

Background

The most distinctive attributes of the mature sperm cell are its streamlined shape and its ability to move independently. This motility is critical for a spermatozoon to not only reach the site of fertilization in the woman's oviduct, but also to negotiate the layers of cumulus cells surrounding the oocyte, and then to penetrate the zona pellucida in order to fertilize the oocyte.

Perhaps surprisingly, not all human spermatozoa are motile, and because it is important for fertility, sperm motility is therefore an integral part of any clinical semen analysis. Even the most basic semen analysis provides an estimate of the proportion of sperm that are motile (i.e. show at least some movement of the tail), while more sophisticated analyses also report the proportion with progressive motility (i.e. able to move from one location to another). There is a relationship between the proportion of progressively motile spermatozoa in a semen sample and the likelihood of that man being fertile. There is also evidence that the concentration of seminal spermatozoa with certain movement patterns (kinematic parameters) is related to the same endpoint.

Determining the relative speed of movement of spermatozoa can be achieved in real-time by highly-trained laboratory scientists, but determining the kinematics of each sperm trajectory requires some sort of image capture and analysis. Historically, this was achieved with the use of photo- and cine-micrographic recordings of sperm movement. The film was then replayed slowly and the position of each sperm cell in successive frames traced onto paper. Although motility, and therefore the spermatozoon's trajectory, is a product of the movement of the sperm tail, it was the position of the sperm head that was traced, as it is the most prominent feature of the spermatozoon and the most likely to stay in focus. Once the trajectory of each spermatozoon in the image had been reconstructed, the tracings were analyzed to determine the speed of movement of each cell, and to derive other kinematic values (e.g. [Katz and Dott, 1975](#); [David et al., 1981](#)). As videomicrography became more accessible, recordings of sperm movement were made on videotape, and the tracks reconstructed manually on plastic sheets attached to the video monitor.

The kinematic values that are most commonly used today were developed by the research group in Kremlin-Bicetre in Paris ([David et al., 1981](#)). As the field expanded, a range of definitions and terminologies were developed for these kinematic values, leading to a significant amount of confusion. In a series of consensus meetings (reported in [Mortimer, 1990](#)), standardized terminology and definitions were developed and these were adopted by the World Health Organization for presentation in their laboratory manuals since 1992 ([Fig. 1](#)). These kinematic values are:

- Curvilinear velocity (VCL; $\mu\text{m/s}$), the length of the actual path followed by the spermatozoon as a function of time, reported to 1 decimal place;
- Average-path velocity (VAP; $\mu\text{m/s}$), the length of the smoothed path followed by the spermatozoon as a function of time, reported to 1 decimal place;
- Straight-line velocity (VSL; $\mu\text{m/s}$), the "net space gain" (distance between the first and last track points) as a function of time, reported to 1 decimal place;
- Linearity ($\text{LIN} = \text{VSL}/\text{VCL} \times 100$; %), a comparison of the lengths (and therefore relative shapes) of the straight-line and curvilinear paths, reported as an integer percentage;
- Straightness ($\text{STR} = \text{VSL}/\text{VAP} \times 100$; %), a comparison of the lengths (and therefore relative shapes) of the straight-line and average paths, reported as an integer percentage;
- Wobble ($\text{WOB} = \text{VAP}/\text{VCL} \times 100$; %), a comparison of the lengths (and therefore shapes) of the average and curvilinear paths, reported as an integer percentage;
- Amplitude of lateral head displacement (ALH; μm), the full width of the curvilinear path (rather than a true amplitude), reported as either a mean or maximum value, to 1 decimal place; and
- Beat cross frequency (BCF; Hz), a de facto expression of the flagellar beat frequency, calculated as the number of times the curvilinear path crosses the average path as a function of time, reported to 1 decimal place.

Originally, the kinematic values were derived empirically for each manually-reconstructed sperm trajectory, meaning that any experiment requiring sperm movement analysis involved many hours of labor-intensive track reconstruction and analysis.

Fig. 1 Kinematic values. Sperm head trajectory showing the derivation of the paths used in velocity calculations (i.e. for VCL, VAP, and VSL) as well as for the ratios (LIN, STR, and WOB) and beat-cross frequency (BCF). Track width is indicated, demonstrating how ALH is determined. Explanations for each of these terms is given in the text.

However, the development of the personal computer in the 1980s and the arrival of digitizer cards meant that these processes could be automated, with data delivered in a fraction of the time. These advances led to the development of commercial CASA instruments. Although there is a range of CASA instruments available now, they all share the general configuration of an optics system (either a stand-alone microscope or microscope components built into the instrument itself), a camera, a more-or-less stand-alone computer (incorporating a digitizer if an analog camera is used), and a display screen. For integrated systems, such as the Hamilton Thorne IVOS, the computer system also has I/O (i.e., input/output) functions to control features such as specimen temperature, illumination intensity, etc.

Technology

The first commercial CASA instruments were developed by CellSoft (Cryo Resources, New York, NY, USA) and by Hamilton-Thorn Research (Beverly, MA, USA) in the mid-1980s. The general concepts were similar for both instruments, with a 0.5–1 s video grab of sperm movement down the microscope (representing 15–30 consecutive images, assuming an image sampling frequency of 30 Hz), followed by identification of each sperm cell in the field of view, reconstruction of each sperm track (based on the movement of the sperm head), and derivation of the kinematic values for each track. Image sampling frequency refers to the number of images per second that are analyzed, expressed as Hz. The oldest CASA systems used 25 or 30 Hz, depending on the video system used (PAL or NTSC), rather than 50 or 60 Hz, the minimum image sampling frequency to describe the trajectory effectively (Mortimer et al., 1988).

The resolution of the images at that time was not good, and so there were problems with other cells, or debris, being identified as sperm cells. In addition, the computing power was quite low, so in this first generation of CASA instruments it still took several minutes (or even longer) for the reconstruction and kinematic analysis steps for each field.

Over the next 30 years, improvements in computing power and image acquisition have been reflected in the development of vastly improved CASA instruments. Now, it is possible to acquire 60 images per second and with almost instantaneous assessment of the kinematic values for each cell in the field. Significantly faster camera “shutter speeds” mean it is also now possible to image the sperm tail, so it might not be too much longer before it is possible to make direct assessments of flagellar movement, rather than relying on assessment of sperm head movement as a proxy.

In the meantime, we continue to rely upon sperm head assessment as the general approach for routine CASA assessments. To ensure that the sperm head can be imaged successfully, negative-high (NH) phase contrast optics are used when acquiring the images for assessment. NH optics show the sperm head as a white dot against a black background, so it is much more obvious. Once the machine has identified a white dot, it determines whether it is a sperm head based on dimensions pre-set by the user (the “gates”). In the most modern instruments, the machine also performs a perimeter assessment to identify a tail, which gives further confirmation that this is, in fact, a sperm head. Once each sperm cell in the field of view has been identified, the program then sets a zone of probability around each sperm head, which is a user-defined estimate of the maximum distance it would be likely (or possible) for the sperm head to travel from one image to the next (Fig. 2). When the next image in the sequence is assessed, the program identifies the most likely relationship between the sperm heads in the previous image and the sperm heads in the current image, and then connects the images to create a path for each spermatozoon. This is repeated for all of the images acquired in the sequence, and then the kinematic values are calculated for each trajectory.

There are some problems that can arise with this approach. For example, if cells enter or leave the field during the sequence, how can these trajectories be assessed? For cells that leave the field, it is possible to set a minimum number of images that are assessed before a trajectory can be included in the analysis, so any that meet this criterion could still be included. For cells that enter the field after the first image has been acquired, their trajectories are not included in the assessment, as there was no zone of probability established in the initial sequence analysis.

Similarly, in the earlier versions of CASA, if two or more cells were in the same zone of probability, it was not possible to be certain whether the correct trajectory would be followed, or whether different part-trajectories had been joined up in error. The more modern systems have solutions for this problem, including vector analysis of trajectories, relying on the assumption that each spermatozoon is more likely to continue in its established direction of travel. Of course, this is not necessarily going to be true if the sperm cells collide with each other, as the collision itself could force a change in direction. This potential problem is one of the reasons that there is a restriction on the sperm concentration in samples to be assessed by CASA, typically in the range of 60–80 million/mL (depending on the CASA instrument).

In addition to sperm concentration, there are several other technical factors that can affect the accuracy and applicability of CASA results, including chamber depth and image sampling frequency. Ideally, all the spermatozoa in the original field of view will remain in focus for as long as they stay in the field. If a sperm head were to go out of focus, the apparent change in the size of the head, or the brightness or contrast, could cause it to fall outside the expected limits, and the CASA instrument would truncate the track at that point. Choosing the magnification to use is a balance between ensuring the image is large enough to allow discrimination between sperm heads and other cells or debris, while maintaining a sufficient depth of focus. For human sperm samples, a 10× objective is typically used, due to the relatively small size of the sperm head, but this restricts the chamber depth to around 20 µm to ensure the spermatozoa remain in focus. Sperm in semen have a relatively low-amplitude flagellar wave, so 20 µm depth does not restrict their movement patterns. However, spermatozoa that have been removed from seminal plasma and washed into culture medium have a much broader range of flagellar movement, with amplitudes of up to 10 µm (i.e., 20 µm from peak to trough). In this case, a preparation depth of 30 µm would be preferable, to reduce the risk of contact

Fig. 2 Zone of probability. Once the CASA instrument has identified a sperm cell, it assigns a centroid at the center of the sperm head (shown as a black dot), and defines a “zone of probability” for where the sperm cell is expected to be in the next image (A). The CASA instrument then checks the next image to determine whether a sperm head is in the zone of probability. When it locates one, it assigns a centroid and a trajectory is started (B). If there is more than one sperm head in the zone of probability (C), the CASA instrument must either determine which is the more likely to be the sperm cell that is being tracked (for example via vector analysis), or truncate the trajectory at that point, with the associated risk of losing that trajectory from the analysis.

between the sperm tail and the chamber walls, but this requires the user to confirm whether too many sperm tracks were being truncated.

Given all of the technological requirements for effective CASA, it is not surprising that quality control is a critical aspect in ensuring that the instrument is working properly and that the results obtained are reproducible. In addition, some certification and licensing agencies require that quality control procedures be performed every day before any other assessments are done. For example, variations in the illumination intensity and in the gate sizes used to define the size of the sperm head can affect the ability of the CASA instrument to identify sperm correctly, which is a major factor in ongoing QC/QA. There are a number of solutions for this type of assessment, including the use of beads or fixed sperm suspensions of known concentration, or the analysis of standard recordings of sperm with known concentration and motility values, or the manual inspection of individual CASA-derived trajectories of spermatozoa from fresh semen samples to ensure that the instrument is correctly identifying all of the sperm cells in the field of view. Each approach has advantages and disadvantages, so the approach chosen for each lab should address the aspects of CASA assessment that are the most relevant to the outcomes being reported.

Because CASA supports the assessment of thousands of individual sperm trajectories, a large amount of data are generated for each sample. To save the user from needing to interpret all of this information, most CASA instruments report sample-averaged values in a single screen. While this is of value for sample-related sperm parameter values, such as concentration, % motile, and concentration of progressively motile spermatozoa, it is not useful for the kinematic parameters, as statistically they are not normally distributed. Indeed, each kinematic parameter usually has a wide range of values within a sample, so simply presenting the mean does not provide any useable information. Even worse, if users take the average of the mean kinematic values collected over several microscope fields, the standard deviation (SD) will be very low, thereby accidentally hiding any indication of variability in the measures. As a result, international consensuses have consistently called for kinematic values to be reported as either median and range or as the proportion of sperm tracks that meet pre-determined threshold values, such as the proportion of motile spermatozoa with $VCL \geq 100 \mu\text{m/s}$ (e.g. [ESHRE Andrology Special Interest Group, 1998](#)). Presenting the kinematic data in this way allows meaningful comparisons between test and control samples, and provides a better indication of the effect of an intervention on sperm function.

Research Applications

CASA is an extremely powerful tool for studying changes in sperm motility in response to experimental interventions, such as exposure to pharmaceuticals or to environmental toxicants, and in reproductive epidemiology studies ([Perreault, 2002](#)). In these applications, researchers are able to determine the relative effect of the exposures on the proportion of progressively motile sperm in a sample, as well as on aspects of sperm function, such as hyperactivated motility.

Fig. 3 Flagellar and head traces (HA vs non-HA). (A) Demonstrates the difference between the sperm head trajectories of a non-hyperactivated spermatozoon and a hyperactivated spermatozoon, drawn using the same magnification. Although CASA follows the sperm head, it is the sperm tail wave that determines the head trajectory. (B) Shows the difference between the tail movement patterns of hyperactivated and non-hyperactivated spermatozoa, as traced (left side of panel), and in a composite (right side of panel), drawn using the same magnification.

Hyperactivated (HA) motility, first described by [Yanagimachi \(1970\)](#), is characterized by a whiplash-type of flagellar movement, and is a concomitant of sperm capacitation, a range of maturational changes that confer to the spermatozoon the capacity to fertilize an oocyte. HA is induced by one or more signaling factors present in the ampulla of the periovulatory female reproductive tract, triggering Ca^{2+} influx in the sperm flagellum via CatSper1 Ca^{2+} protein channels ([Suarez, 2008](#)), and there is evidence that HA motility is a critical factor in sperm-egg interaction (reviewed by [Mortimer, 1997](#)). There is a significant difference in the range of flagellar movement of HA and non-HA spermatozoa, and this translates to differences in the sperm head trajectories ([Fig. 3](#)). As a result, HA motility cannot be reliably identified by eye, so CASA is required. The complexity of the trajectories also means that there isn't any single kinematic parameter that can define HA motility reliably, and so Boolean arguments are used. The definition for HA motility in the rodent uses a combination of the kinematic parameters VSL, ALH and LIN ([Suarez 2008](#)), while the definitions for human spermatozoa use a combination of VCL, ALH and LIN, or VCL and D (fractal dimension) ([Mortimer et al., 1998, 2015](#)).

CASA is also of value in the objective assessment of sperm morphology, particularly in species with relatively large sperm heads. Abnormal morphology is an indication of perturbations in the development of spermatozoa in the testes, and so it can serve as a functional marker of exposure to reproductive toxicants, and a predictor of reduced fertility. This information is invaluable in research studies of the effects of new pharmaceuticals, and in environmental exposure studies.

Clinical Applications

Although the concept of CASA arose from the need to study sperm movement, there has long been a hope that CASA could provide a reliable, objective method of semen analysis for clinical diagnostic use. While this is already a standard approach for a range of

animal species, this has not been the case for human semen assessments. This difference is primarily due to the relatively homogeneous nature of semen from domesticated and other animal species, which contains mostly motile spermatozoa with few other cell types, and the very heterogeneous nature of human semen, which contains many immotile spermatozoa as well as a range of other cell types and debris. As a result, it is relatively simple for the CASA instrument to accurately identify and track sperm heads in animal semen, whereas in human semen there has been a high risk of mis-identification of sperm heads, with the associated risk of under- or over-estimating sperm concentration and % motile. However, if human semen analysis by CASA was used to estimate the concentration of progressively motile spermatozoa in the ejaculate, the results would be much more accurate.

This functional approach to semen analysis is based on the observation that semen samples that contained at least 25×10^6 progressively motile sperm/ml (defined as trajectories that met the criteria: VAP $> 25 \mu\text{m/s}$ AND STR $> 80\%$ AND ALH $> 2.5 \mu\text{m}$) were more likely to have normal results in sperm-cervical mucus penetration tests, while samples that did not meet these criteria had abnormal results (Mortimer et al., 1986). The ability of spermatozoa to penetrate cervical mucus is a critical factor in fertility in vivo in many species, including human. The mucus in the cervix represents a physical barrier to the entry of spermatozoa into the female reproductive tract, so spermatozoa that are unable to penetrate cervical mucus are therefore unable to participate in fertilization.

Future Applications of CASA

As the image acquisition capabilities and computing power increase, perhaps in concert with artificial intelligence that will support machine learning, there will be more applications for CASA in research and clinical settings. It is likely that these applications will predominantly be using fixed and stained spermatozoa, providing a fast, objective method for the assessment of whole-cell morphology/morphometry. Multiparametric evaluation of sperm morphology provides an index-based estimate of the average number of abnormalities per abnormal sperm, giving an indication of the quality of testicular function in sperm production. This type of evaluation requires the assessment of not only the sperm head, but also the midpiece and tail. Until now, imaging the midpiece and tail has been a challenge, but CASA instruments are now gaining this capability and so it will be possible in the near future to perform this assessment automatically and objectively once the results have been validated against reference methods.

Other assays that could be performed by CASA in the future include sperm vitality assessment and sperm chromatin dispersion, which provides an indication of sperm DNA integrity.

Another future application of CASA is the use of a smart phone to perform sperm motility and concentration assessments (Kanakasabapathy et al., 2017). Again, the results need to be verified against those obtained using reference methods, but it is possible that this use of technology will allow sperm assessment in the absence of a laboratory.

Introduction

Worldwide reports suggest that infertility affects 15%–20% of couples of reproductive age and about 50% of these are accountable to the male partner. While men with infertility represent a significant percentage of the infertile population, public awareness of this fact is limited at best. Literature and the other media have often neglected the male component of reproduction other than its sexual nature. Wider access to male infertility assessment may help to resolve this deficiency.

Semen analysis is the key element in the diagnosing the reproductive potential of a man with fertility in question. In current practice men must use a clinic or other hospital facility to have their semen analyzed. Once at the clinic, they are asked to produce a semen sample, which is then analyzed by staff at the clinic. Many subjects are not comfortable with this procedure, which they often find embarrassing and expensive.

A diagnostic test that men could perform in the privacy of their own home could lead to substantial improvement in this area. Many devices were invented to solve these problems. In this article, we show the commercialized devices to test semen sample at home **Table 1**.

Home Semen Microscope Evaluation Kits

Over-the-counter microscopes that are directly marketed to the consumer are also available to perform home semen analysis. Some companies produce and sell kits that include a conventional microscope, slides, and other accessories to analyze semen sample. A Medline literature review did not reveal studies that have evaluated the performance of these kits compared with semen analysis performed by a laboratory.

Chromatographic Immunoassay ~ SpermCheck Fertility®

The SpermCheck Fertility test is a rapid qualitative test designed to detect the presence of sperm in human semen. This test was approved by the US FDA. The test employs solid-phase chromatographic immunoassay technology and consists of a immune-chromatographic strip in a single cassette. The test strip is calibrated to give a positive result if the sperm concentration is 15×10^6 sperm/mL or greater. The device employs a pair of monoclonal antibodies which bind distinct, nonoverlapping epitopes on the sperm acrosomal antigen SP-10. Similar kinds of immune-chromatographic strips are available (**Fig. 1**).

Table 1 Summary of home semen test

Type of testing	Method	Evaluation items	Limitation	Cost	The available number of times
Microscope evaluation kit	Conventional microscope	Sperm concentration Sperm motility	High cost, Conflicting/ lacking data Must count sperm by themselves	USD \$100–500	Unlimited
SpermCheck®	Chromatographic immunoassay	Sperm concentration 5×10^6 sperm/mL and above 20×10^6 sperm/mL and above	Fail to evaluate sperm motility	USD \$39.99	1 test
Trak®	Centrifuge	Three categories of sperm concentration low (≤ 15 M/mL), moderate (15–55 M/mL), and optimal (> 55 M/mL)	Fail to evaluate sperm motility	USD \$199.99	4 tests
YO®	Smartphone based device	Motile sperm concentration as normal (above 6.0 M/mL) or low (below 6.0 M/mL)	Supportive data lacking	USD \$49.95	2 tests
Men's loupe®	Ball lens microscope with smartphone	Sperm concentration Sperm motility	Must count sperm by themselves	USD \$15	4 tests

Fig. 1 SpermCheck fertility kit.

Centrifugal Method ~ Trak® Male Fertility Testing System

The Trak® Male Fertility Testing System (Sandstone Diagnostics, Livermore, CA) is a centrifugal microfluidic device for measuring sperm concentration in the home. The device, which recently received 510(k) clearance from the US FDA, provides linear sperm concentration measurement with three category (two cutoff) semiquantitative results: low (≤ 15 M/mL), moderate (15–55 M/mL), and optimal (> 55 M/mL). This categorical approach combines the WHO threshold with an evidenced-based reference value for faster time to pregnancy (**Fig. 2**).

The Trak device comprises a battery-powered reusable instrument (Engine), single-use test cartridges (Props), and various consumables. The Props use centrifugal force to process a defined volume of semen and visually display sperm concentration.

Fig. 2 (A) Trak® engine. (B) Trak® prop.

To operate the system, a user collects a semen sample in an enzyme-coated collection cup that promotes liquefaction (viscosity reduction). The user transfers approximately 0.25 mL of semen to the Prop inlet chamber, attaches the Prop to the Engine, and closes the lid to initiate the spin sequence (~6.5 min at 7000 rpm). As the Prop spins, a precise volume of semen is metered by centrifugal action from the sample inlet into the metering chamber, and sperm are compacted into a narrow channel at the end of the Prop. When the spin sequence is complete, the sperm cells form a visible, measurable white column that is proportional to the concentration of sperm in the sample and visually interpreted by the user. The system also includes an external control comprising a bead suspension formulated to simulate Trak results at a calibrated sperm concentration. Users may run the control on a Prop to verify proper operation of the system components, as well as to practice the assay protocol before testing a semen sample.

The Trak System includes multiple tests and encourages users to track changes in sperm concentration over time. A companion mobile app (Trak: Sperm Health & Fertility) provides users with personalized recommendations on health and lifestyle changes that may improve sperm concentration and chances of conception.

Smartphone Based Home Semen Test

YO® Home Sperm Test

The YO® Home Sperm Test was developed by the same team at Medical Electronic Systems that developed the SQA line of automatic semen analyzers used in over 4000 hospital labs, universities, and IVF centers globally. YO was cleared by the FDA in late 2016 and received a CE mark in early 2017. This system is comprised of a clip which attaches to the top of the smartphone thereby turning it into a microscope, a fixed cover slip plastic test slide that is inserted into the clip along with liquefaction powder (chymotrypsin) used to accelerate the liquefaction of the sample. YO measures motile cell concentration (moving cells) with 97% accuracy and reports results as normal (above 6.0 M/mL) or low (below 6.0 M/mL). The user can view and store a live video of his sperm and can receive an automatic test result within 2 min after liquefaction (Fig. 3).

Ball Lens Microscope ~ Men's Loupe®

A Dutch scientist, Antonie van Leeuwenhoek, first discovered the spermatozoon in 1677 using a ball lens microscope that he had invented. This simple device consisting of ball lens microscope (Leeuwenhoek's microscope) paired with a state-of-the-art smart phone equipped with a camera of the kind found in nearly all commercial smart phones. Sperm concentration and motility calculated with ball lens showed a very strong correlation with the CASA results (Fig. 4).

This microscope has been commercialized as "Men's loupe" (Tenga Health Care, Tokyo, Japan). The advantage of this device is very cheap due to a simple structure.

Smartphones have great potential to analyze semen because they are portable, contain excellent digital cameras and can be easily attached to a microscope. A ball lens microscope is inexpensive and easy to use for acquiring digital microscopic movies. Given its small size and weight, the device can support testing for male fertility at home or in the field, making it much more convenient and

Fig. 3 YO® Home sperm test.

Fig. 4 Men's loupe®.

economical than current practice. In addition, microscopy using smartphones offers additional capabilities such as telediagnosis, store-and-forward imaging, live-streaming of video, and the development of software enabling complex image analyses. This ball lens microscope provides an easy solution for global users to rapidly screen male infertility.

Conclusion

The advent of such new technologies and the democratization of fertility testing may upend the traditional approach to couples. Now, with such ease of access to home screening for abnormal bulk semen parameters, the male partner may pursue formal evaluation by a reproductive specialist before the female partner. With the use of a high-quality home semen test, even if the results are only semiquantitative, traditional attitudes toward male-factor infertility are already changed. Infertile couples will begin to initiate their own evaluations. Due to its accessibility, home semen testing may offer the potential to expand the public understanding of male-factor infertility.

Laboratory Evaluation of Azoospermia

Grace M Centola, New York, NY, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Azoospermia is defined as the complete absence of sperm cells (spermatozoa) in the ejaculate. Approximately 1% of all men suffer from azoospermia, with up to 15% of men found to have no sperm (Jarow et al., 1989; Oates, 2012; Gudeloglu and Parekattil, 2013).

The causes of azoospermia are varied but include genetic (congenital), obstructive or nonobstructive, and unknown or idiopathic reasons. Genetic causes of azoospermia include hormonal abnormalities, Y chromosome microdeletions, absence of any sperm-producing cells (referred to as Sertoli cell only syndrome), and dysfunction of these sperm-producing cells (Gudeloglu and Parekattil, 2013). Obstructive azoospermia occurs in 15%–20% of azoospermic men and is caused by obstruction or blockage of the tubules or ducts that convey the sperm from the testicles to the outside. This includes ejaculatory dysfunction which prevents the semen from passing through the ducts and tubules during the ejaculatory process. Nonobstructive azoospermia occurs when the absence of sperm results from defects in sperm production. Congenital bilateral absence of the vas deferens (CBAVD) occurs when the vas deferens (the tube through which the sperm are transported) is missing from birth. Retrograde ejaculation, in which the semen is transported backward into the bladder rather than outward through the urethra, is also a form of nonobstructive azoospermia. In the case of retrograde ejaculation, sperm production is usually normal and the problem is often neurological, prohibiting antegrade or outward passage of sperm through the vas deferens. In most cases of retrograde ejaculation, sperm can be retrieved from the urine and used for assisted reproduction. Additional acquired causes of obstructive azoospermia include testicular trauma, infections including mumps orchitis, reproductive tract tumors, medications and recreational drug use, surgery and systemic diseases such as liver cirrhosis and kidney failure which prevent ejaculation through normally occurring ducts and tubules (Gudeloglu and Parekattil, 2013).

A thorough history and physical exam, as well as hormone evaluation, and semen analyses are important steps in the evaluation and diagnosis of azoospermia and could assist in formulation of an appropriate treatment plan, if possible, for these individuals.

Laboratory Evaluation of the Azoospermic Male

Azoospermia is diagnosed following microscopic examination of the semen. Generally two to three separate semen specimens will be examined by trained laboratory technologists. Each semen specimen should be collected 3–4 weeks apart and delivered to the laboratory within 30–45 min after ejaculation. Alternately, the specimens can be collected by masturbation in a private room provided at the laboratory facility.

The laboratory technologist will then prepare a wet-mount slide of the well-mixed semen specimen by placing a drop of the semen on a glass slide and covering with a thin glass coverslip. The specimen smear on the slide is carefully examined using a light microscope for the presence of spermatozoa. If no sperm are found on the slide, a second slide will often be prepared using a new drop of well-mixed semen. Additionally, a semen smear can be preserved and stained to confirm the absence of sperm and permanently document the laboratory findings.

If no sperm are found after scanning all areas of the slides, the semen can be centrifuged into a small pellet, and the pellet is examined for the presence of sperm (Jaffe et al, 1998; Corea et al, 2005; WHO, 1999). The pellet, containing all cellular components as well as noncellular debris, is then smeared onto a clean glass slide and carefully examined under the microscope for the presence of sperm. If even a low number of sperm is found, semen specimens may be frozen and stored for later use in assisted reproduction (Jaffe et al, 1998; Corea et al, 2005; WHO, 2010; Oates, 2012). When few sperm are found, the condition is referred to as severe oligozoospermia or cryptozoospermia (WHO, 2010; Gudeloglu and Parekattil, 2013).

Centrifugation of a semen specimen is recommended in cases of post vasectomy semen analysis (WHO, 1999). The WHO (2010) laboratory manual and the American Urological Association (AUA) (Sharlip et al, 2017) suggest that centrifugation is not necessary to confirm the presence of rare nonmotile sperm, suggesting that careful slide examination of the raw semen may be sufficient (Korthorst et al., 2010). Furthermore, Steward and colleagues (2008) concluded that examination of an uncentrifuged, raw semen specimen is sufficiently reliable for identifying >100,000 sperm. Since centrifugation might interfere with sperm motility, the AUA suggests that clinically relevant numbers of sperm can be identified without centrifugation (Sharlip et al, 2017).

Nonetheless, if no sperm are observed after careful examination of the raw semen specimen (duplicate slides as mentioned above), it is the standard and acceptable laboratory procedure to examine a centrifuged semen specimen for the presence or absence of sperm in order to correctly and reliably report a diagnosis of azoospermia.

Two other important parameters of the semen analysis—semen volume and pH—can provide useful information as to the cause of azoospermia (Oates, 2012). Approximately 10% of the ejaculate volume is contributed by the testicles, 70% by the seminal vesicles, and 20% from the prostate gland. The seminal vesicles provide alkaline fluid, while the prostate gland provides acidic fluid. Hence, the semen is alkaline since the seminal vesicles provide the majority of the fluid in the normal ejaculate (Oates, 2012). A low volume, low pH (acidic), azoospermic semen specimen is primarily made up of fluid from the prostate gland, suggesting absence of the seminal vesicles, bilateral absence or blockage of the vas deferens, or bilateral blockage of the ejaculatory ducts (Oates, 2012).

Alternately, in an azoospermic male, if the semen volume is normal, and the semen is alkaline, the seminal vesicles are presumably functional and duct obstruction is not a consideration. A blockage may be at a level closer to the testicles, or sperm production might be compromised in the testicle. Careful examination of centrifuged semen with a diagnosis of azoospermia can, in the case of normal volume and alkaline semen, confirm testicular failure. If even a few sperm are found in an ejaculate, testicular production of sperm is confirmed, albeit reduced, and blockage of the ducts, or absence of the vas deferens would not be possible (Oates, 2012).

Precise laboratory examination of both raw and centrifuged semen, measurement of semen volume and pH, along with evaluation of complete medical history, physical exam and hormone analyses, can confirm a diagnosis of azoospermia or complete absence of sperm in the ejaculate. Following such a diagnosis, a treatment algorithm can be individualized for each patient for purposes of reproduction.

Seminal Hypo- and Hypervolemia

Rajasingam S Jeyendran and Milica Ivanovic, Androlab Inc., Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Semen volume is the quantity of ejaculate produced and represents the sum of secretions from the accessory sex glands (seminal fluid) as well as sperm and other cellular components. Seminal fluid is comprised mainly of secretions by the seminal vesicles and prostate gland, with a small amount from the bulbourethral glands and epididymis. The seminal vesicles contribute approximately 75% of the ejaculate volume; the prostate provides another 20% and the remaining secretions, spermatozoa, and non-sperm cells make up approximately 5% of the ejaculate. During ejaculation, the bulbourethral gland secretions are emitted first, representing a small drop of fluid. Subsequently, the prostatic secretions as well as the majority of the spermatozoa are ejaculated, followed by the seminal vesicle secretions. By obtaining a “split ejaculate” (collecting the first and subsequent fractions of an ejaculate in two different containers), these secretions can be roughly separated.

An adequate volume of ejaculate during coitus is necessary to transport the spermatozoa to or near the cervix. An abnormal volume may help indicate why a couple has failed to conceive and thus recording the ejaculate volume is an important component of a semen analysis report. Similarly, the total volume of semen is used to calculate the total number of sperm in the ejaculate.

Even if the sperm concentration and motility are well within the acceptable limits, given the nature and consistency of the ejaculate especially if it is viscous, it can be difficult to measure the semen volume accurately. A precise measurement by weighing the sample and then calculating the volume from the weight is advocated by [WHO laboratory manual \(2010\)](#). However for Practical reasons we recommend the semen volume to be measured to the nearest 0.1 mL with a graduated pipette, centrifuge tube, or syringe.

For clinical interpretation, one needs to define what constitutes an abnormal ejaculate volume. [WHO laboratory manual \(2010\)](#) provides a lower reference value of 1.5 mL based on 1941 fertile men. In the author's own laboratory analyzing ejaculates from 3690 male spouses of infertile couples 701 (19%) had less than 1.5 mL. A deeper review of the results revealed a wider distribution within this group; 15 (0.4%) men produced no ejaculate or less than 0.1 mL and 93 (2.5%) men produced less than 0.5 mL.

It is generally thought that the seminal plasma is supportive to spermatozoa rather than being essential for their function, but the biochemical analysis of the seminal plasma can be useful for diagnostic purposes. Individual components of seminal plasma are more than likely not essential for sperm function so that they are not useful as fertility indicators but only to assess the reason if the semen volume is affected. In the author's own experience and clinical interpretation of semen analysis results ([Jeyendran, 2000](#)) it is recommended that the ejaculate volume be classified as:

- Aspermia and Anejaculate: no ejaculate following orgasm.
- Hypovolemia if the ejaculate is 0.5 mL or less.
- Hypervolemia if the ejaculate is more than 6.0 mL.

Outline

Semen volume may identify fertility impairing pathology of the male.

Aspermia and Anejaculate

This condition is defined as the absence of an antegrade ejaculate following orgasm or a very small semen volume (less than 0.1 mL) following ejaculation ([Kamischke and Nieschlag, 1999](#); [Mieusset et al, 2017](#)). In this situation, voided urine sample following masturbation must be evaluated for the presence of fresh sperm. If spermatozoa are present, then retrograde semen flow back into the bladder has occurred and the condition is referred to as retrograde flow of semen (commonly and erroneously referred to as: “retrograde ejaculation”). Normally, the urinary sphincter is closed during ejaculation to prevent retrograde semen flow into the bladder. If the sphincter fails to contract for whatever reason, the ejaculate may flow back into the bladder rather than proceed through the urethra. The following underlying causes can produce this condition:

- transurethral or open surgical resection of the bladder neck or prostate
- bilateral sympathectomy
- bilateral retroperitoneal lymphadenectomy
- extensive pelvic surgery (particularly proctectomy and colectomy)
- diabetic visceral neuropathy
- antihypertensive drugs that block sympathetic tone
- spinal cord injury

Hypovolemia

The hypovolemia is clinically relevant since it may affect fertility of the male. It is often due to factors that can be broadly classified into artifactual, behavioral, biological, psychogenic, and pathologic causes ([Roberts and Jarvi, 2009](#)).

Note: Hypovolemia has a minimal or no effect on spermatozoon fertilizing potential.

Artifactual Causes

The sexual stimulatory signals are modulated from higher brain centers, and therefore semen quality and quantity depend in part on the degree of psychological arousal.

Studies have demonstrated that collection of semen during actual coitus (using a seminal pouch) yields higher ejaculate quality and quantity than that obtained through masturbation in the laboratory environment.

An insufficient period of sexual abstinence between ejaculations will influence the ejaculate volume.

[WHO \(2010\)](#) reference value for semen volume is based on 2–7 days of sexual abstinence, but it is generally recommended the ejaculate be collected after 2–3 days of sexual abstinence.

Incomplete collection (partially missing the container) or spillage following sample collection will affect the semen volume determination.

Behavioral Causes

Recreational drugs such as heroin or methadone acting through higher brain centers may indirectly influence semen volume ([Nudell et al, 2002](#)).

Semen volume tends to decrease with increasing cigarette consumption ([Pasqualotto et al, 2006](#)).

Biological Causes

Patient age appears to affect the semen volume. As men age, the semen volume decreases ([Eskenazi et al, 2003](#)).

A 50-year-old man may have a 20% less semen volume compared to a 30-year-old man.

Psychogenic Causes

Anorgasmia due to anxiety, stress, disapproval, and embarrassment about masturbation may lead to partial ejaculation. Appropriate counseling or repeat collection on a different day may be advisable ([Roberts and Jarvi, 2009](#)).

Under certain emotional stress such as the recent diagnosis of cancer, one may produce poor ejaculate quality prior to semen analysis and cryopreservation.

Pathologic Causes

Hypovolemia without spermatozoa in the semen, and with a pH less than 7.4 could be due to ejaculatory duct obstruction or congenital absence of the seminal vesicles ([Roberts and Jarvi, 2009](#)).

Semen chemistries should be investigated. Such symptoms are associated with either partial or complete absence of fructose (produced by the seminal vesicles). However, normal zinc and acid phosphatase content with acidic pH (produced by the prostate gland) should be present.

Hypovolemia with spermatozoa present in semen and with a pH less than 7.4 could be due to obstruction of the seminal vesicular opening by a mucus-like plug, producing a high sperm concentration ([Perez-Pelaez et al, 1988](#)).

The obstructing plug may dissolve spontaneously, causing resumption of normal ejaculate volumes; but more often than not the obstacle actually enlarges, causing azoospermia over time.

Stricture of the seminal vesicular duct, probably due to inflammation, may also result in this condition.

Hypovolemia without (or low numbers of) spermatozoa in semen and with pH more than 7.8 could be due to hypoandrogenism leading to impaired spermatogenesis, while some fructose may still be present ([Jeyendran, 2000](#)).

Hypovolemia with spermatozoa present in the semen and with a pH greater than 7.8 could be due to a partial or incomplete retrograde flow of semen.

Post ejaculate; voided urine must be examined ([Kamischke and Nieschlag, 1999](#); [Mieusset et al, 2017](#)).

This condition may also be due to accessory sex gland impairment caused by inflammation or cancer (especially if the pH is more than 9.0; [Jeyendran, 2000](#)).

Other factors that appear to affect ejaculate volume include dietary zinc deficiency ([Hunt et al, 1992](#)), HIV -1 infection ([Bujan et al, 2007](#)), Klinefelter syndrome ([Aks glaede et al, 2009](#)), and certain drugs such as Silodosin and Tamsulosin ([Nudell et al, 2002](#)).

Hypervolemia

There is no clear cut point above which the seminal volume becomes pathologic, but the upper limit for normal has been reported to be 6 mL (Eliasson, 1976; Cooke et al, 1995; Jeyendran, 2000; Zhang et al, 2015). The determination of hypervolemia is generally not relevant clinically but should be noted. It is often due to either a long period of sexual abstinence or accessory sex gland fluid overproduction. (In the author's own laboratory experience, 4% of the men produced more than 6 mL; the largest volume measured from a single ejaculate was 15.8 mL.)

Note: Hypervolemia has a minimal or no effect on spermatozoon fertilizing potential.

With the increasing interest in sperm function testing and nearly routine use of intracytoplasmic sperm injection with assisted reproductive technologies, clinicians treating male infertility are sometimes only interested in obtaining sperm from the male rather than identifying or correcting any underlying etiology and pathology. This notion may suggest that the determination of ejaculate volume may no longer be important. It should be emphasized however that the measurement of semen volume is an essential part of routine semen analysis since it may help identify and correct fertility impairing pathology which may allow couples to conceive without resorting to advanced assisted reproductive technologies.

Laboratory Evaluation of Leukocytospermia

Grace M Centola, Reproductive Laboratory and Tissue Bank Consultant, Port St Lucie, FL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Normal semen specimens from fertile men will contain varying amounts of debris and other cell types as well as live and dead sperm. Leukocytes, predominately polymorphonuclear leukocytes (granulocytes or neutrophils) are present in all semen specimens (Tomlinson et al., 1992; Moskovtsev et al., 2007; WHO, 2010). When an unstained smear on a slide is observed under a microscope, it is not possible to distinguish whether the round cells are leukocytes or immature sperm cells, both of which appear as round cells and of similar size. When more than one round cell is seen under the microscope in multiple high power magnified areas, special staining is usually done to distinguish the WBCs from other types of cells (Mortimer, 1994; WHO, 2010). Generally, the presence of one round cell seen in the high magnification fields is a concentration of approximately one million WBCs per ml, which is commonly accepted as a normal level for WBCs in semen (WHO, 2010; Sikka and Hellstrom, 2016). Leukocytospermia is defined as excessive numbers of WBCs or leukocytes in the semen (WHO, 2010), in excess of one million/ml.

The clinical significance of semen white blood cells (WBCs) remains controversial (Moskovtsev et al., 2007; Palermo et al., 2016). Increased seminal WBCs may suggest a urogenital infection or inflammation (Pentyala et al., 2007; Duan et al., 2014; Fraczek et al., 2016; Palermo et al., 2016). An elevated leukocyte count, even as high as 30%, however, has been observed in the absence of urogenital inflammation or bacterial infection (Palermo et al., 2016). Negative effects of increased WBCs on sperm concentration and motility, sperm function and male fertility have been reported (Fedder, 1996; Arata de Bellabarba et al., 2000; Moskovtsev et al., 2007). A decrease in sperm concentration, motility and normal morphology, and an increase in oxidative stress has been seen with increased semen WBCs (Moskovtsev et al., 2007; Fraczek et al., 2016). Furthermore, increased semen WBCs was correlated with increased presence of abnormal sperm, particularly, with head damage, and midpiece and tail defects (Aziz et al., 2004). However, increased WBCs in the semen on the day of oocyte retrieval did not influence outcomes in in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI) (Yilmaz et al., 2005; Ricci et al., 2015), while other studies have shown negative effects (Tomlinson et al., 1992; Lackner et al., 2008; Seshadri et al., 2012). Interestingly, moderate leukocyte concentration (< one million/ml) is considered normal and has been associated with increased fertilization and pregnancy rates (Barraud-Lange et al., 2011; Palermo et al., 2016).

Laboratory Evaluation of Leukocytospermia

Several methods have been used to distinguish between leukocytes, immature sperm cells and other round cells in semen (Mortimer, 1994; WHO, 2010; Ricci et al., 2015). Methods used to identify the types of round cells in the semen include special staining, cytochemical analysis, and labeling with special antibodies (Moskovtsev et al., 2007; WHO, 2010). Seminal leukocytes can be differentiated from immature sperm cells by differences in coloration when stained, and on the size and shape of the cell nucleus (Johanisson et al., 2000; WHO, 2010). Neutrophils, or granulocytes, the most common type of WBCs in semen, are characterized by the presence of granules in the cell cytoplasm, which will be visible after using special stains.

Staining

A stained slide is routinely used to determine normal and abnormal spermatozoa (see Laboratory Evaluation of Morphology). However, a morphology slide can also be used to estimate the presence of multi-nucleated immature sperm cells, polymorphonuclear cells (showing distinctive lobulated nucleus), and lymphocytes (large round or kidney shaped nucleus) all of which show a distinctive coloration and nuclear structure on a stained slide (Mortimer, 1994; Johanisson et al., 2000; WHO, 2010).

Common stains used to differentiate round cells (leukocytes and immature sperm cells) in semen are Papanicolaou, Shorr and Giemsa stains (Menkveld and Kruger, 1998; Johanisson et al., 2000; Moskovtsev et al., 2007; WHO, 2010). Using these stains, leukocytes appear blue in color, while immature sperm appear pink (WHO, 2010). Some granulocytes demonstrate fewer cytoplasmic granules, and a round or kidney shaped nucleus. The polymorphonuclear leukocytes (PMNs) have a characteristic large lobulated nucleus, with inter-nuclear bridges connecting the lobes, while immature sperm actually have multiple nuclei in one cell. On a stained slide, these differences can be readily seen and the leukocyte concentration estimated.

Peroxidase Staining

Since granulocytes are the majority of WBCs in semen, a routine method to distinguish these cells from other round cells is a stain that shows peroxidase activity in the cytoplasmic granules (Johanisson et al., 2000; WHO, 2010). The characteristic granules can be stained using o-toluidine which stains the peroxidase in the granules. Peroxidase positive cells stain brown, while negative cells are unstained. It is important to note that other types of WBCs (i.e., lymphocytes) do not have peroxidase-positive granules,

and thus, will not stain brown using this type of methodology (Menkveld and Kruger, 1998; Johanisson et al., 2000). Since the granulocytes are the majority of leukocytes in the semen, an estimate of the total WBC concentration can be made using the peroxidase staining. The concentration of the peroxidase-positive leukocytes is made based on the cells with brown-stained granules and the sperm concentration. It is important to note that the peroxidase stain method does not enumerate the non-granular WBCs and the immature sperm cells both of which contribute to the round cell concentration in the semen. Laboratory test kits are commercially available for determination of the granulocyte concentration (LeucoScreen, Vitrolife, Inc., Englewood, CO, USA; FertiPro N.V., Belgium).

Advanced Assays

Additional advanced testing can be used to distinguish between leukocytes, immature sperm cells or other round cells, although these tests are not routinely performed in the clinical andrology laboratory. The significance of these tests is questionable, and may not provide additional information to the clinician useful for management of the infertile male. One advanced test determines binding of unique surface proteins on the round cell membrane. One such protein is called CD45, which is present on the surface of leukocytes (Duan et al., 2014; Palermo et al., 2016). The surface protein on the round cell membrane can be tagged with a stain or label which would then be detected by specialized equipment. Similar assays include monoclonal antibody binding to leukocytes and alkaline phosphatase staining (Mortimer, 1994).

Flow cytometry has also been used for precise counting of seminal leukocytes, and has been considered more sensitive and specific than staining methods, particularly the peroxidase method (Ricci et al., 2015). Flow cytometry uses laser technology to excite probes bound to the surface of the cell. The probes give off light which is then detected by an electronic detection instrument (Perticarari et al., 2007; Ricci et al., 2015). Flow cytometry provides a simple, rapid, and highly accurate method for evaluation of several semen parameters, including leukocyte concentration (Perticarari et al., 2007). However, flow cytometry is not a standard instrument in clinical andrology laboratories, and hence, the importance of this technique for determination of semen leukocytes has not been realized.

Conclusion

Even though the clinical significance of seminal round cells has been questioned, the presence of an abnormally elevated concentration of round cells should be further evaluated. Approximately 15% of male infertility cases present with infectious etiologies (Jung et al., 2016), and, may or may not be accompanied by elevated leukocytes. It has been shown that an elevation of the semen WBC concentration may be deleterious to sperm count, motility and morphology, and increase oxidative stress on the sperm (Pentyala et al., 2007; Jung et al., 2016). Accurate determination of the WBC concentration in semen allows the clinician to determine a course of treatment. Antibiotic and antioxidant administration has become a widely accepted treatment to reduce semen WBCs, and the effects on sperm concentration, motility and oxidative stress (Lackner et al., 2006; Pentyala et al., 2007; Fraczek et al., 2016; Jung et al., 2016).

Laboratory Evaluation of Antisperm Antibodies

Grace M Centola, Reproductive Laboratory and Tissue Bank Consultant, Port St Lucie, FL, United States

Introduction

The presence of antisperm antibodies in semen, blood (serum), cervical mucus, vaginal secretions and in follicular fluid which surrounds the egg, can be a significant cause of infertility. The clinical relevance of such antisperm antibodies, however, remains controversial, since these antibodies can be present in both fertile and infertile men (Chiu and Chamley, 2004; Zini et al., 2011; Sikka and Hellstrom, 2009). Numerous publications report antisperm antibodies in infertile men ranging from 9 to 36% (Naz, 2004), 9–13% (Chiu and Chamley, 2004), 5–15% (Ombelet et al., 2009; Zini et al., 2011) and 10–30% (Sikka and Hellstrom, 2009). As many as 60% of vasectomized men have serum antisperm antibodies (Parslow et al., 1983; Sikka and Hellstrom, 2009). Yet sperm antibodies have been found in as many as 3% of fertile men and 4% of fertile women (Chiu and Chamley, 2004; Ombelet et al., 2009).

Antisperm antibodies can cause a decrease in sperm concentration and motility, as well as a longer seminal fluid liquefaction time (Cui et al., 2015). Sperm antibodies have been shown to cause decreased sperm motility, clumping or agglutination of sperm, impairment of sperm-cervical mucus penetration, impaired sperm-egg interaction and post-fertilization events (Lombardo et al., 2001, 2004; Bjorndahl et al., 2010; Zini et al., 2011; Restrepo and Cardona-Maya, 2013; Vasquez-Levin et al., 2014; Cui et al., 2015). Furthermore, the presence antisperm antibodies has resulted in decreased fertilization rates (45–34%) and decreased pregnancy rates (11% versus 44%) when the male partner has sperm antibodies as compared to those who do not have sperm antibodies (Chiu and Chamley, 2004; Vasquez-Levin et al., 2014).

When performing a semen analysis, the laboratory will scan a slide to determine the quality of motility and progression of the sperm. Antisperm antibodies may be present when spermatozoa show a decrease in percent motility with an increase in non-progressive motile sperm (shaking in place, “tic-toc” movement). Furthermore, sperm antibodies may cause sperm to stick to each other (head to head, tail to tail, or in a mixed way) (WHO, 2010). Antisperm antibodies can also cause repeated abnormal sperm-cervical mucus interaction testing (PCT). Testicular trauma or injury, persistent leukocytospermia and repeated genital infections may also result in sperm antibodies (Sikka and Hellstrom, 2009).

Antisperm antibodies are only relevant if there is significant interference with fertilization-related processes (Naz, 2004; Sikka and Hellstrom, 2009, 2016; WHO, 2010). However, the nature and identity of antigens on the sperm surface that interfere with the fertilization process are not clear (Bjorndahl et al., 2010).

In the presence of significant agglutination and/or unexplained reduced sperm motility, testing should be considered to determine if these abnormalities are caused by the presence of sperm antibodies. Some laboratories include antibody screening as part of routine semen analysis regardless of the appearance of agglutination or immobility of the sperm. Several tests are available to assess the presence of immunological infertility. Testing includes direct tests, that is, test for the presence of antibody directly on the sperm surface, and indirect tests, that is., test for the presence of antibody in body fluids such as serum, cervical mucus, follicular fluid.

Direct Tests for Antisperm Antibodies

Current direct sperm antibody tests include the mixed antiglobulin reaction (MAR) test and the immunobead binding test (IBT). These tests are performed on a fresh semen specimen and requires at least 200 motile sperm for the test to be valid (Bjorndahl et al., 2010).

The MAR test is an inexpensive, quick and sensitive screening test (Bjorndahl et al., 2010; WHO, 2010). In this test, a “bridging” second antibody is used to attach antibody-coated latex beads to sperm that have surface antibodies (Sikka and Hellstrom, 2009; Bjorndahl et al., 2010; WHO, 2010). An earlier MAR test used sensitized red blood cells before the antibody-coated beads were developed (Mortimer, 1994; Sikka and Hellstrom, 2009).

Fresh, unwashed sperm are mixed on a glass slide with a drop of the antibody-coated latex beads and a drop of antiserum. After approximately 2–3 min, the slide is examined under the microscope. Sperm that have attached latex beads are those that are antibody positive. Although the MAR test is simple and cost-effective, it does not show the location of the antibody on the sperm surface or the class of antibody. This location and class of antibody is important in determining the clinical significance of the antisperm antibodies. In the MAR test, when 10% or more of sperm are clumped with latex beads, a more specific test, such as the Immunobead Binding Test (IBT) should be done (Sikka and Hellstrom 2009, 2016). Others suggest a value of 50% clumping in a MAR test for a test to be considered positive. Several kits for MAR testing are available commercially for laboratory use.

The Immunobead Binding Test (IBT) is a more specific antibody test which identifies the class or type of antisperm antibody and the binding site on the sperm surface (head, midpiece, tail) by using different size or color polyacrilamide beads corresponding to the immunological class of antibody (referred to as immunoglobulin type A (IgA) and immunoglobulin type G (IgG)). In this test, a drop of washed sperm is mixed with a drop of the individual type of bead. After a 2–3 min incubation, the slide is observed under a microscope (Sikka and Hellstrom, 2009; Bjorndahl et al., 2010; WHO, 2010). The beads will adhere to those sperm that have

antibodies on their surface. When greater than 20% of sperm have at least two beads attached, the test is considered a positive test. The test, however, is clinically significant only when greater than or equal to 50% of the motile sperm have attached beads (Sikka and Hellstrom, 2009, 2016; Bjorndahl et al., 2010; WHO, 2010). IBT kits are commercially available for clinical laboratory use.

Indirect Tests for Antisperm Antibodies

Indirect antibody tests are used to detect antisperm antibodies in sperm-free fluids such as serum, seminal plasma, cervical mucus and follicular fluid (WHO, 2010; Vazquez-Levin et al., 2014). An antibody negative donor sperm sample is incubated with the test fluid. This sperm specimen is then tested using a direct test (IBT) to see if sperm antibodies in the fluid bind to the sperm.

A known antibody negative sperm sample is washed and a fraction of motile sperm is recovered for use in the test. The motile sperm are incubated with the heat-inactivated test fluid for 1h. Next the sperm are washed to remove the test fluid, and are then mixed with immunobeads as in a direct IBT. As in the direct IBT, the sperm with attached beads are positive for sperm antibodies and those with no attached beads are negative (Sikka and Hellstrom, 2009, 2016; Bjorndahl et al., 2010; WHO, 2010). Both the class of antibody and the location on the sperm (head, midpiece, tail) are recorded and used to determine the test result. In the indirect test, at least 50% of the motile sperm must have attached beads in order for the test to have clinical significance (Bjorndahl et al., 2010; WHO, 2010). Known negative and positive samples, such as serum from a known positive and a known negative male, must also be tested as control samples.

Conclusion

The presence of antisperm antibodies is not a clear-cut indicator of infertility since fertile men and women can present with sperm antibodies. The presence of antisperm antibodies can be evaluated using a direct test on sperm or an indirect test using other body fluids. At least 50% of the sperm must show positive for antisperm antibodies in order for the test to be clinically significant. A report of a clinically significant positive antisperm antibody test should be followed by additional tests such as the sperm-cervical mucus interaction test, or compared to results of a post-coital test. However, antisperm antibodies may still cause infertility by affecting sperm-egg interaction, with no impairment of sperm penetration of the cervical mucus. Treatment for antisperm antibodies include drug treatment (immunosuppressive drugs), intrauterine insemination and IVF and ICSI. ICSI has been shown to be the primary choice for treatment of immunological infertility, especially in severe cases and with head-bound antibodies (Lombardo et al., 2001, 2004; Naz, 2004; Zini et al., 2011).

Glossary

Chemiluminescence Is the emission of light as a result of a chemical reaction.

Colorimetry Is a technique used to test the concentration of a colored compound in a solution by measuring absorbance of a specific wavelength of light.

Free radical Is an atom, molecule or ion that has an unpaired valence electron. The unpaired electrons make free radicals highly reactive chemically towards other substances.

Peroxidation Is a type of reaction in which oxygen atoms are formed leading to oxidation to the greatest extent especially in formation of a peroxide.

Posttranslational modifications Regulates protein functions by chemical modifications after translation. The reactions include phosphorylation, ubiquitination, methylation, acetylation, glycosylation and nitrosylation, carbonylation.

Proteomics Refers to the application of biotechnology in analyzing the structure, function, and interactions of proteins produced by the genes in a particular biological system.
